COLE & ELMAN

TEXTBOOK of SURGERY

WARREN H. COLE, M.D.
Professor and Head of the Department of Surgery, University of Illinois College of Medicine; Chief Surgeon, Illinois Research and Educational Hospitals, Chicago

with

49 Contributing Authors and Consultants

Foreword by EVARTS A. GRAHAM

Appleton-Century-Crofts, Inc.
New York

559–13

Library of Congress Card Number: 59–5263

PRINTED IN THE UNITED STATES OF AMERICA

To

DR. EVARTS AMBROSE GRAHAM

and

DR. ROBERT ELMAN

Who have exerted great influence on my professional career. Their loyal friendship and inspiration will always be remembered.

CONTRIBUTING AUTHORS AND CONSULTANTS

LeROY C. ABBOTT, M.D.
Emeritus Professor of Orthopaedic Surgery, University of California School of Medicine, San Francisco
Fractures, Dislocations, and Sprains

WILLARD M. ALLEN, M.D.
Professor of Obstetrics and Gynecology, Washington University School of Medicine; Obstetrician and Gynecologist, Barnes and St. Louis Maternity Hospitals; Gynecologist St. Louis Children's Hospital
Gynecololgy

WILLIAM ALTEMEIER, M.D.
Christian R. Holmes Professor and Chairman, Department of Surgery, University of Cincinnati and Cincinnati General Hospital
Chemotherapy in Surgery

R. KIRKLIN ASHLEY, M.D.
Clinical Instructor in Orthopaedic Surgery, University of California Medical Center; Chief of Orthopaedics, University of California Service, San Francisco General Hospital; Assistant Surgeon, Shriner's Hospital for Crippled Children, San Francisco Unit; Attending Surgeon, Hospital for Women and Children and Franklin Hospital, San Francisco
Fractures, Dislocations, and Sprains

GLENN BELL, M.D.
Professor of Surgery, University of California School of Medicine, San Francisco
Mammary Gland

FRANK B. BERRY, M.D.
Assistant Secretary of Defense (Health and Medical); Emeritus Professor of Clinical Surgery, College of Physicians and Surgeons, Columbia University; Consulting Surgeon, Bellevue Hospital; Brigadier General (M.C.), U.S.A.R. (Ret.)
Military Surgery

ALFRED BLALOCK, M.D.
Professor of Surgery and Director of the Department of Surgery, Johns Hopkins University; Surgeon-in-Chief, Johns Hopkins Hospital
Shock and Hemorrhage

THOMAS H. BURFORD, M.D.
Professor of Thoracic Surgery, Washington University School of Medicine; Associate Surgeon, Barnes and St. Louis Children's Hospitals
Surgical Diseases of the Thorax

JACK A. CANNON, M.D.
Associate Professor of Surgery, University of California Medical Center, Los Angeles; Consultant, Los Angeles USVA Hospital, St. John's Hospital, Santa Monica, and Santa Monica Hospital
Blood Vessels

ROBERT J. COFFEY, M.D.
Professor and Director, Department of Surgery, Georgetown University Medical Center, Washington, D.C.
Cancer

WARREN H. COLE, M.D.
Professor and Head of the Department of Surgery, University of Illinois College of Medicine; Chief Surgeon, Illinois Research and Educational Hospitals, Chicago

FREDERICK A. COLLER, M.D.
Emeritus Professor of Surgery, University of Michigan Medical School
The Peritoneal Cavity

DENTON ARTHUR COOLEY, M.D.
Associate Professor of Surgery, Baylor University College of Medicine; Attending Surgeon, Jefferson Davis, Methodist, and Veterans Administration Hospitals; Consultant, Texas Children's Hospital, Lackland Air Force Base, and Brooke Army Chemical Center
Cardiovascular Surgery

E. STANLEY CRAWFORD, M.D.
Assistant Professor of Surgery, Baylor University College of Medicine; Attending Surgeon, Methodist, St. Luke's Episcopal, Veterans Administration, and Jefferson Davis Hospitals, Houston
Cardiovascular Surgery

OSCAR CREECH, M.D.
William Henderson Professor and Chairman, Department of Surgery, Tulane University

School of Medicine; Chairman of Surgical Service, Charity Hospital; Consultant in Surgery, Touro Infirmary
Laboratory Aids in Surgery

MICHAEL E. De BAKEY, M.D.
Professor and Chairman, Cora and Webb Mading Department of Surgery, Baylor University College of Medicine; Surgeon-in-Chief, Jefferson Davis Hospital; Chief Consultant in Surgery, Veterans Administration Hospital; Senior Attending Surgeon, Methodist Hospital, Houston
Cardiovascular Surgery

CLARENCE DENNIS, M.D.
Chief of Surgery, Kings County Hospital; Professor and Chairman, Department of Surgery, State University of New York Downstate *Medical Center, Brooklyn*
The Alimentary Tract

R. D. DRIPPS, M.D.
Professor and Chairman, Department of Anesthesiology, University of Pennsylvania Schools of Medicine, Philadelphia
Anesthesia

J. ENGLEBERT DUNPHY, M.D.
Kenneth A. J. Mackenzie Professor of Surgery and Head of the Department, University of Oregon Medical School. Formerly, Professor of Surgery, Harvard Medical School; Director of Sears Surgical Laboratory and Fifth Surgical Service, Boston City Hospital
The Surgical History and Examination

CHARLES ECKERT, M.D.
Professor and Chairman, Department of Surgery, Albany Medical College of Union University; Surgeon-in-Chief, Albany Hospital
The Lymphatic System

*ROBERT ELMAN, M.D.
Professor of Clinical Surgery, Washington University School of Medicine; Assistant Surgeon, Barnes Hospital; Associate Surgeon, St. Louis Children's Hospital; Chief of Staff and Director of Surgical Service, H. G. Philips Hospital, St. Louis

THOMAS B. FERGUSON, M.D.
Assistant Professor of Surgery, Washington University School of Medicine; Attending Surgeon, Barnes, Cochran Veterans Administration, St. Louis Children's, St. Louis City, and Allied Hospitals
Surgical Diseases of the Thorax

*Deceased.

PAUL W. GREELEY, M.D.
Clinical Professor of Surgery and Head of the Division of Plastic Surgery, University of Illinois College of Medicine; Senior Attending Plastic Surgeon, University of Illinois Research and Educational Hospitals and Presbyterian-St. Luke's Hospital, Chicago
Fractures, Dislocations, and Sprains

R. ARNOLD GRISWOLD, M.D.
Professor of Surgery, University of Louisville School of Medicine; Surgical Staff, Norton Memorial Infirmary
Wounds

JAMES D. HARDY, M.D.
Professor and Chairman, Department of Surgery, and Director of Surgical Research, University of Mississippi Medical Center; Surgeon-in-Chief, Hospital of the University of Mississippi; Chief Surgical Consultant, Jackson Veterans Hospital and Mississippi Tuberculosis Sanatorium
Surgical Convalescence

WILLIAM D. HOLDEN, M.D.
*Oliver H. Payne Professor and Director, De*partment of Surgery, Western Reserve University School of Medicine; Director of Surgery, University Hospital of Cleveland
Fluid, Electrolyte, and Caloric Balance

JOHN M. HOWARD, M.D.
Professor and Chairman, Department of Surgery, Hahnemann Medical School; Consultant in Surgery, Philadelphia Veterans Ad*ministration Hospital and Walter Reed Army* Medical Center; Consultant in Thoracic Surgery, Wilkes-Barre Veterans Administration Hospital
Systemic Reaction to Trauma

CHARLES G. JOHNSTON, M.D.
*Professor of Surgery, Wayne State Univer*sity College of Medicine; Director of Surgery, Detroit Receiving Hospital and Veterans Administration Hospital
Intestinal Obstruction

EDWARD T. KREMENTZ, M.D.
Associate Professor, Department of Surgery, Tulane University School of Medicine; Visiting Surgeon, Charity Hospital
Laboratory Aids in Surgery

WILLIAM P. LONGMIRE, JR., M.D.
Professor and Chairman, Department of Surgery, University of California Medical Center, School of Medicine, Los Angeles
Blood Vessels

CHARLES C. LUND, M.D.
Clinical Professor of Surgery, Harvard Medical School; Surgeon-in-Chief, Fifth Surgical Service, Boston City Hospital
Thermal, Chemical, and Electric Trauma

CHAMP LYONS, M.D.
Professor and Chairman, Department of Surgery, Medical College of Alabama
Acute Surgical Infections

CYRIL MacBRYDE, M.D.
Associate Professor of Clinical Medicine, Washington University School of Medicine, St. Louis; Assistant Physician, Barnes Hospital; Director, Metabolism and Endocrine Clinics, Washington University
The Endocrine Glands

FRANCIS M. McKEEVER, M.D.
Associate Clinical Professor of Surgery (Head of Orthopaedic), University of Southern California School of Medicine; Senior Orthopaedic Surgeon, Los Angeles County General Hospital and Children's Hospital
Amputations

LELAND S. McKITTRICK, M.D.
Clinical Professor of Surgery, Harvard Medical School; Surgeon, Massachusetts General and New England Deaconess Hospitals
Surgery in Diabetes; Medical Ethics and Conduct

GEORGE C. MORRIS, JR., M.D.
Assistant Professor of Surgery, Baylor University College of Medicine; Attending Surgeon, Methodist and Jefferson Davis Hospitals, Houston; Consultant in Surgery, Texas Children's and Veterans Administration Hospitals, Houston
Cardiovascular Surgery

CARL MOYER, M.D.
Bixby Professor of Surgery and Head of the Department, Washington University School of Medicine, St. Louis
Ulcers and Gangrene

JOHN H. MULHOLLAND, M.D.
George David Stewart Professor and Chairman, Department of Surgery, New York University College of Medicine; Director, Third (N.Y.U.) Surgical Division, Bellevue Hospital
The Pancreas

REED NESBIT, M.D.
Professor of Surgery, Section of Urology, University of Michigan; Chief, Section of Urology, University Hospital
The Genitourinary System

E. J. POTH, M.D.
Professor of Surgery, University of Texas Medical Branch, Galveston
Bacterial Inflammation

I. S. RAVDIN, M.D.
John Rhea Barton Professor of Surgery, University of Pennsylvania School of Medicine; Director, Harrison Department of Surgical Research, University of Pennsylvania School of Medicine; Surgeon-in-Chief, University Hospital, University of Pennsylvania, Philadelphia
Liver, Gallbladder, and Bile Ducts

WILLIAM REQUARTH, M.D.
Assistant Clinical Professor of Surgery, University of Illinois College of Medicine
The Hand

C. P. RHOADS, M.D.
Director, Sloan-Kettering Institute for Cancer Research; Scientific Director, Memorial Center for Cancer and Allied Diseases; Professor of Pathology, Department of Biology and Growth, Sloan-Kettering Division of Cornell University Medical College
Cancer

JOHN SCHNEEWIND, M.D.
Associate Professor of Surgery and Chief of Emergency Service, Illinois Research Hospitals; Assistant Attending Surgeon, Presbyterian-St. Luke's Hospital; Consultant, Hand Surgery, Veterans Administration Hospital, Hines, Illinois, and West Side Veterans Administration Hospital, Chicago; Associate, Cook County Hospital
The Emergency Service

CARLO S. SCUDERI, M.D.
Clinical Associate Professor of Orthopedic Surgery, University of Illinois College of Medicine; Senior Attending Surgeon, Cook County Hospital; Chairman, Department of Orthopedic Surgery, St. Elizabeth and Columbus Hospitals; Senior Orthopedic Surgeon, Alexian Brothers Hospital, Chicago
Fractures, Dislocations, and Sprains

W. EUGENE STERN, M.D.
Associate Professor of Surgery (Neurological Surgery), University of California, Los Angeles; Chief, Division of Neurological Surgery, U.C.L.A. Medical Center and Wadsworth Veterans Administration Hospital
The Nervous System

ROGER D. WILLIAMS, M.D.
Assistant Professor of Surgery, Ohio State University College of Medicine
The Spleen

PHILIP D. WILSON, M.D.
Director of Research, Hospital for Special Surgery, New York; Emeritus Clinical Professor of Surgery (Orthopaedics) Cornell Medical College
The Organs of Movement

NATHAN A. WOMACK, M.D.
Professor of Surgery, University of North Carolina School of Medicine; Chairman, Department of Surgery, North Carolina Memorial Hospital
A Brief Background of Surgery

ROBERT M. ZOLLINGER, M.D.
Professor and Chairman, Department of Surgery, Ohio State University College of Medicine
The Spleen

Preface

Since publication of the last edition we have suffered an irreparable loss in the death of Robert Elman. His broad knowledge of the field and his many attributes as a splendid teacher of surgery were vital to the success of this volume. He contributed a great deal to this revision, but he died before final copy could be prepared. Our hope is that we have maintained the same high standard of excellence which has characterized the contributions of Doctor Elman to earlier editions.

This edition has been completely revised and completely rewritten with new material. Nine new chapters and 297 new figures have been added. The book begins with a brief history of surgery written by Doctor Nathan Womack. Dr. Oscar Creech and Dr. E. T. Krementz have contributed a chapter dealing with laboratory tests and aids. Traumatic injuries are increasing in number, and a chapter on the systemic reaction to trauma by John Howard has been added to the book. Cancer incidence, etiology, dissemination, and principles in diagnosis and treatment are discussed anew. Two new chapters on the heart and great vessels, one dealing with congenital lesions and the other with acquired lesions, by Michael De Bakey and his associates are included for the first time. Medical conduct and ethics are explained to the student.

We have made great changes in the remaining chapters. Much new material has been added by many new contributors.

Physiology has been stressed and the needs of the student have been continually kept in mind. Nonsurgical treatment is described in detail, and the principles of operative treatment are presented. Numerous illustrations of gross specimens and photomicrographs will be found throughout the text.

We are indebted to many friends for valuable assistance in preparation of various chapters. Among them are Dr. Leo Sachar, Dr. Arthur Stein, Dr. Myron Wheat, Dr. Frank Richards, Dr. James Hunter, and others. We wish also to express our sincere appreciation to Miss Josephine Magista, Mrs. Ruth Scapino, Mrs. Doris Peterson, and Mrs. Florence Bagnall for their untiring secretarial assistance. Mr. Hooker Goodwin and his staff in the Illustrations Studios have contributed many new drawings. The publishers have at all times manifested the utmost cooperation in preparation of this revision.

WARREN H. COLE, M.D.

CONTENTS

Foreword

The object of this book has been to present a *systematic survey of the field of surgery.* Obviously in the space of one volume an attempt could be made only to deal with those aspects of surgery which would seem to be the most important. It is not easy to make a satisfactory selection of those topics which actually are *the most important. Different surgeons* would doubtless have various opinions concerning what subjects actually are the most important and, therefore, deserve the most emphasis. Especially would this be true in regard to many of the conditions which have now, by more or less com*mon consent, fallen into the realm of* some one of the specialized subdivisions of surgery. This book reflects the effort which has consistently been made to give rather more information about those matters with which every general practitioner should be familiar than to attempt *to cover the entire field of surgery.*

With the enormous development of surgery during the present century it has become increasingly more difficult to prepare a work which could properly be called a *Textbook of Surgery.* For such a book should be small enough *to be encompassed in one volume and at the* same time be sufficiently comprehensive to give the student a reasonable amount of information concerning those surgical conditions with which every medical student should be more or less familiar. To prepare such a work has been a *challenge* which *many* authors have accepted. Many of the results have been excellent but there is a rather widespread feeling among surgical teachers that the ideal text has not yet been written. Perhaps it never will be. Certainly no book could hold a first rank place for a long period of *time without frequent revisions* because of the necessity to incorporate within it the rapid changes in points of view, in methods of diagnosis, in the treatment and even in the conceptions of what diseases may properly be regarded as having surgical aspects. As one reviews the changed conceptions concerning what conditions have surgical aspects he is forced to the realization that nowadays there are scarcely any diseases in which the advice of the surgeon may not be sought. Within the years of the present century almost incredible changes have occurred. Pulmonary tuberculosis, certain aspects of nephritis, heart diseases, malignant hypertension, cancer of the lung, hyperinsulinism, hyperparathyroidism, to mention a few, have already been transformed from conditions which presumably had no surgical implications to ones which now demand space and attention in any *comprehensive work on surgery. Endocrinology,* one of the newest medical sciences, is now, from a therapeutic aspect, largely a surgical problem. When one contrasts the present scope of surgery, therefore, with its scope when it was largely the practice of external medicine, he of necessity *realizes that the writing of a satisfactory text*book becomes increasingly difficult as time goes on.

Dr. Cole and Dr. Elman have appreciated that, because of the necessities involved, a textbook of surgery should have certain qualities. In *order to encompass the material in a single* volume conciseness is a prime requisite and, of necessity, many things have to be omitted which it would be desirable to have in the book. It seems to me that they have carried out their object in a remarkable manner. The various surgical conditions are excellently described as are also the accepted methods of treatment. On the other hand, they have very rightly in such a book paid but scant attention to the conceptions and the treatment of the diseases in question which are too new to have been given a sufficient trial. Moreover, by eliminating many relatively unimportant details, the authors have felt justified in expecting the student to become familiar with all of the material included in the text. Obviously, of course, no limits should ever be placed on the amount of reading of current and other literature; *indeed, further outside reading* is demanded of the student. To aid him, an extensive bibliography has been included. Elaborate descriptions of operations are not given because such material is presented in the various systems of surgery and it hardly deserves a place in a book of this kind. The principles involved in the various operative procedures, however, are stated. It is futile to attempt to make an undergraduate student a finished surgeon. To accomplish that purpose years of postgraduate study and experience are required. Nothing, therefore, would be gained by including within this book extensive and detailed descriptions of operations.

The book should be found to be very helpful, not only to undergraduate students but also to general practitioners who desire to obtain in a concise manner information about many of the advances which have been made in surgery. Even the experienced surgeon will find the book helpful for the same reason.

TEXTBOOK of SURGERY

1

A BRIEF BACKGROUND OF SURGERY

NATHAN A. WOMACK

One might well ask why, in a textbook of contemporary surgery, space should be devoted to a consideration of surgery of the past, a surgery that has already been accepted and become commonplace, or concepts and principles that have been thrown into discard. Many reasons could be suggested for such a study, any one of which would be adequate for the thoughtful and critical student and perhaps none of which would satisfy the most pragmatic. The latter could say, and occasionally with good justification, that to learn only what is known now will enable him to practice adequately the surgery that should be done now. But what is known now? What are the things we should believe to be fact and what are those we should not accept? Certainly we learn very quickly that the opinions of those in authority are ephemeral indeed. We thus can learn contemporary surgery, but how can we evaluate it? How can we be assured of its truth?

Speaking in a different context, Lord Acton once said, "The living do not give up their secrets with the candor of the dead; one key is always excepted and a generation passes before we can insure accuracy. Common report and outward seeming are bad copies of the reality as the initiated know it. . . . The use of history turns far more on certainty than an abundance of acquired information." One has only to glance through the pages of a surgical journal a decade or two old to see the truth in this statement.

We can say then that a firm background in the knowledge of the past, both in general and in specific subjects, will give us a clearer understanding of the present. We can see the path by which the present was reached. On rare occasions we are enabled to see even a few steps into the future.

The story of surgery differs from that of the arts or of politics or of the law in that it has been slowly cumulative. Even so, it has not developed as a cold, experimental discipline but has often been discontinuous. There have been periods of close association with political and ecclesiastical history, many times to the detriment of surgery, rarely to its advantage. It has nourished itself on wars. It has suffered from the numerous restraints on education. Einstein has said of great advances in scientific theory that they occur in the manner of quantum jumps, being discontinuities rather than logical progressions. And so it has been with surgery. These jumps have occurred during those periods of a "disregard for inherited sanctions" where little has been taken for granted.

In studying the past, one sees that surgery is not a simple vocation concerned only with the sale of services. In the deep urge to relieve the pain and torture of mankind there appears constantly a tremendous idealism rising above the commonplace of the day and giving hope to all mankind. Of such has surgery been built. Here are both scientific values and human values of a high order indeed. Here is the unbridled triumph of the individual in pursuing these efforts. This is the heritage, then, that the past gives the con-

1

A BRIEF BACKGROUND OF SURGERY

NATHAN A. WOMACK

One might well ask why, in a textbook of contemporary surgery, space should be devoted to a consideration of surgery of the past, a surgery that has already been accepted and become commonplace, or concepts and principles that have been thrown into discard. Many reasons could be suggested for such a study, any one of which would be adequate for the thoughtful and critical student and perhaps none of which would satisfy the most pragmatic. The latter could say, and occasionally with good justification, that to learn only what is known now will enable him to practice adequately the surgery that should be done now. But what is known now? What are the things we should believe to be fact and what are those we should not accept? Certainly we learn very quickly that the opinions of those in authority are ephemeral indeed. We thus can learn contemporary surgery, but how can we evaluate it? How can we be assured of its truth?

Speaking in a different context, Lord Acton once said, "The living do not give up their secrets with the candor of the dead; one key is always excepted and a generation passes before we can insure accuracy. Common report and outward seeming are bad copies of the reality as the initiated know it. . . . The use of history turns far more on certainty than an abundance of acquired information." One has only to glance through the pages of a surgical journal a decade or two old to see the truth in this statement.

We can say then that a firm background in the knowledge of the past, both in general and in specific subjects, will give us a clearer understanding of the present. We can see the path by which the present was reached. On rare occasions we are enabled to see even a few steps into the future.

The story of surgery differs from that of the arts or of politics or of the law in that it has been slowly cumulative. Even so, it has not developed as a cold, experimental discipline but has often been discontinuous. There have been periods of close association with political and ecclesiastical history, many times to the detriment of surgery, rarely to its advantage. It has nourished itself on wars. It has suffered from the numerous restraints on education. Einstein has said of great advances in scientific theory that they occur in the manner of quantum jumps, being discontinuities rather than logical progressions. And so it has been with surgery. These jumps have occurred during those periods of a "disregard for inherited sanctions" where little has been taken for granted.

In studying the past, one sees that surgery is not a simple vocation concerned only with the sale of services. In the deep urge to relieve the pain and torture of mankind there appears constantly a tremendous idealism rising above the commonplace of the day and giving hope to all mankind. Of such has surgery been built. Here are both scientific values and human values of a high order indeed. Here is the unbridled triumph of the individual in pursuing these efforts. This is the heritage, then, that the past gives the con-

mporary surgeon. It is well worth a serious udy.

This brief chapter can give the reader all o little of this heritage. The good historian ust always consult intimately the source aterial just as the good scientist consults e source background of his experimental oblem. For the busy surgeon this is impos- ble. It requires time and a knowledge of lan- iages, modern and ancient, that few of us ossess. There must be available an unusual orary as well as detachment and patience. bviously then, in this chapter we will be le to consider only a few facets of our oblem.

In most civilizations, surgery seems to have eceded internal medicine. This is natural cause of the immediacy of physical trauma. ere, help of a practical nature could be ven without dependence upon philosophical eculation. Surgery required only careful servation and such observations, condi- oned as they were by pain, did not require o high a degree of intellectual development. nimals will keep an injured part at rest and, possible, a dirty wound open.

PRIMITIVE SURGERY

Human skulls in which circular fragments bone have been removed as if by trephine ive been found dating back to the Neolithic Polished Stone Period. Evidence of heal- g of the bone shows that there were at least casional instances of survival. It has been sumed that such operations were performed r headache and for epilepsy in order to al- w egress of evil spirits. On the other hand, is known that buttons of bone were used as nulets. Therefore, there may have been ther reasons, perhaps of a religious nature, r the performance of this operation. Cer- inly with the origin of serrated flint instru- ents, surgical procedures became manifest.

It was the feeling of Ruffer that the major- y of trephine openings were made during fe and that those resembling post-mortem rocedures were in patients who died during r shortly after the procedure. Of interest are e skulls in which more than one trephine pening is found in various states of healing. his suggests the probability that the trepan- tion was done for disease, perhaps headache, that was not cured by the first operation. Certainly one must question the concept of Broca, that the skull was trephined on young epileptics or mad subjects to rid them of some "demon," for if Neolithic man possessed the same ideas as those people in more recent times who have been found to have a comparable type of civilization, the epileptic and the insane were considered holy and held in high estate. Trephined skulls have been identified not only in western Europe, but in Switzerland, Romania, Poland, Denmark, Germany, and Sweden. There is no indication that the Chinese or Hindus ever practiced such a procedure, nor have such skulls been uncovered from the Egyptian, Greek, or Roman cultures. In the Western World, previous to the arrival of the Europeans, the operation was unknown among the Indians of the north but was practiced in Mexico and Central America and especially in Peru.

These findings, then, are not limited to any particular culture but seem to be more or less universal. Whether these "elemental ideas" sprang spontaneously in these various groups, a "convergence concept" as introduced by Bostian, or whether by "Convection" as sponsored by Ratzel is a problem for ethnologists and need not concern us here. They all, for the most part, seem to be related to superstition or basic religious notions concerned with spirits, both good and evil, that directed the destiny of man.

Another operation that may have been a superstitious rite is that of amputation of the fingers, noted in the late Paleolithic period perhaps 25,000 years ago. Garrison states that over 200 silhouettes illustrating this procedure have been found on walls of Paleolithic caverns in Spain as well as elsewhere. There is always hazard involved in the interpretation of previous cultures from the vantage point of our own. Some of these practices may not have been entirely a religious ritual. We see an exception insofar as amputation of the foot is concerned in Lawson's study of the early North Carolina Indian (1714):

> The Iroquois or Sinnegars are the most War-like Indians that we know of being always at War, and not to be persuaded from that Way of Living by any Argument that can be used. If you go to

persuade them to live peacably with the Tuskeruros, and let them be one People, and in case those Indians desire and will submit to them, they will answer you they cannot live without War, which they have ever been used to; that if Peace be made with the Indians they now war with all, they must find out some others to wage War; for them to live in Peace is to live out of their Element, War, Conquest, and Murder being what they delight in, and value themselves for. When they take a Slave and intend to keep him to work in their Fields they flea the Skin from the Setting on his Toes to the middle of his Foot, so cut off one-half of his Feet, wrapping the Skin over the Wounds, and healing them. By this cruel Method, the Indian Captive is hindered from making his Escape, for he can neither run fast or go anywhere, but his Feet are more easily traced and discovered. Yet I know one Man who made his Escape from them, though they had thus disabled him, as you may see in my Journal.

In recent years the operation of transmetatarsal amputation has been reintroduced into surgery albeit for entirely different indications.

That medicine and surgery had become well established in western Asia more than 2,000 years before Christ is revealed in the discovery of the *Code of Hammurabi*, written around the twenty-first century before Christ. This Code also gives evidence of the fact that the surgeon's fee and the character of his surgery had become a concern of the government. Portions of the Code have been translated as follows by Leonardo:

> If a physician shall cause on anyone a severe operative wound with a bronze operating knife and cure him, or if he shall open a tumor (abscess or cavity) with a bronze operating knife and save the eye of the patient, he shall have ten shekels of silver; if it is a slave his owner shall pay two shekels of silver to the physician.
>
> If a physician shall make a severe wound with a bronze operating knife and kill him, or shall open a growth with a bronze operating knife and destroy the eye, his hands shall be cut off.
>
> If a physician shall make a severe wound with a bronze operating knife on the slave of a freed man and kill him, he shall replace the slave with another slave. If he shall open an abscess (growth, tumor, cavity) with a bronze operating knife and destroy the eye he shall pay the half of the value of the slave.
>
> If a physician shall heal a broken bone or cure diseased bowels, he shall receive five shekels of silver; if it is a matter of a freed slave, he shall pay three shekels of silver; but if a slave, then the master of the slave shall give to the physician two shekels.

From this we can infer that a practice of surgery existed. It is also apparent that the surgeon was not separated from the physician, at least in title. The true nature of the practice of medicine in ancient Babylonia exists only in a few scant fragments of tablets that have persisted and in copies of tablets of that period that were made in the Assyrian Empire around the seventh century before Christ. As fragmentary as this material is, a good general concept of the type of medicine practiced can be obtained. Treatises were related to diseases of certain areas such as the head and the digestive organs. There was an extensive materia medica and remedies were applied locally, given by mouth, or inserted as suppositories. These remedies seemed to have been used without specific indications, many being prescribed for the same disease. All medicine seems to have been permeated with superstitions and primitive folklore. Knowledge of anatomy or physiology must have been limited. Of great interest is the fact that none of these tablets relating to early Babylonian medicine refers in any way to surgery other than the Code mentioned above. Some future excavation may bring additional discoveries to light.

In sharp contrast is the picture of surgery in early Egypt. In this older civilization, surgery was farther advanced. Several papyri relating to medicine in early Egypt have been discovered and translated, and each contributes to our understanding of the period. Until recently, knowledge was limited to the information based on the Papyrus Ebers, the Berlin and London Papyri, and the Papyrus Hearst, along with fragmentary portions of several smaller special documents. Interestingly enough, the compilations were all written in the period from the early eighteenth to the sixteenth century before Christ. All of these have been valuable.

In 1930 Breasted published his translation of Papyrus Edwin Smith, which apparently is a transcription of a document from the period of the Old Kingdom about 3,000 years

before Christ. It could easily have been written originally by Imhotep, and Breasted feels that such was probably the case. As such it represents the earliest known treatise on surgery. It undoubtedly represents also a portion of a much larger series of dissertations as it for the most part treats only trauma. Forty-eight cases are described in a systematic arrangement, beginning with the head and extending downward, considering first the less serious injury and later the more serious one. This is not a document of recipes and magic. Here one sees logical conclusions arrived at from facts observed on physical examination and opinions based on considerable clinical experience. Such an approach today is commonplace; for that period it is startling, since almost 5,000 years were to elapse before trauma was again to be treated so intelligently.

Examination consisted of looking at the patient, obtaining a history of the injury, and then determining the extent of the injury. The wound would be probed, the patient instructed to make certain motions, and from these observations a diagnosis established. If the prognosis was favorable, certain treatments of a mechanical nature would be carried out. If the prognosis was indubitably fatal, as in compound wounds of the skull involving the brain, no treatment was recommended. In 13 of the cases described after determining the facts from such observations, a diagnosis was determined logically. "These are the earliest surviving examples of observations and conclusions, the oldest known evidences of an inductive process in the history of the human mind" (Breasted). Here, for the first time, we note a knowledge of the nervous control of muscle contraction, the recognition of the brain not only as an organ but as the seat of the mind, the action of the heart, and the relation between the heartbeat and the pulse rate, information that was not to appear again in human writings for 2,500 years. In Case I, counting of the pulse seems to be described, but this is difficult to understand because of the Egyptians' lack of methods by which to measure short periods of time. Even the water clock had not been developed. The earliest known counting of the pulse with a known time measurer was not to be done until Herophilus in the third century before Christ.

While paralysis of certain muscles was noted following injury to specific areas of the brain, apparently no effort was made to explain the quadriplegia that followed fracture dislocation of the cervical vertebrae. The methods of treating a fractured nose and dislocation of the jaw are classical and are used even at the present time.

Perhaps the single greatest achievement in the history of medicine has been the exclusion of demons, spirits, and sin from the explanation of the origin of disease. Not until this was done could true cause–effect relationship be sought for and established. This has been, and even at times still is, a long and laborious task for society to achieve. It is important, therefore, to note disease described by these early Egyptians as "something which his flesh engenders," denoting the separation of disease as well as accident from the demoniacal.

Perhaps the most impressive technical development lay in the treatment of soft tissue injury. A clean, incised wound was sutured. Whether the surgeon learned the use of the suture from the embalmer or vice versa is of no great importance. The value of the immediate closure of a clean wound without the application of any type of ointment or concoction represents accuracy in observation of a high degree. Irregular, ragged wounds were brought together with adhesive strips. These strips were made of linen cloth to which an adhesive gum was applied, and the surgeon is, on several occasions, cautioned to apply two at the same time, exerting traction with each in opposite directions. Large, gaping wounds with loss of substance were not closed. Apparently the damaging effect of dead space had been observed. It was advocated that such wounds be filled with fresh meat and a bandage applied. This was to be removed in 24 hours and the wound filled with honey. It is difficult to imagine a more sterile covering than these two dressings would afford.

The value of fixation in the treatment of fractures was well recognized, although traction was not completely appreciated. The use of reed splints as well as of a rigid type of plaster made from linen bandages impreg-

nated with resin for fixation of fractured sites was common. Fractures were apparently common. In a study of Egyptian cemeteries of a later date from which between 5,000 and 6,000 bodies were exhumed, one person out of every 32 was noted to have had a fractured bone. Shortening was frequently seen, although nonunion and evidence of infection were practically never observed. Since many of these fractures were of the tibia and fibula, at least a considerable number of them must have been compounded.

This period of Egyptian medicine was not without its specialization. Junker describes a tombstone of a palace physician at Gizeh during the period of the Old Kingdom (circa 2500 B.C.). This man, whose name was Iry, possessed among other titles "palace eye physician, palace physician of the belly, and guardian of the anus."

What knowledge of surgery existed in the Old Kingdom other than that of trauma we as yet have little way of knowing. From the fragments of information that have come from studies of other papyri, particularly that of Ebers, it is probable that other phases of surgery had not developed to such a high degree. This held true for what would be considered internal medicine also. Perhaps it was for this reason that such an excellent achievement in the surgery of trauma was to undergo a considerable degree of decay. Mysticism and magic were always in the background and, where ignorance of natural laws was profound, they could easily make their appearance and achieve an ascendency. The late eminent historian of medicine, Henry Sigerist, has postulated that the level of culture of a society has always been reflected in the state of medical knowledge and practice of that society. Such seems to have been true in Egypt, for with a decline in surgical and medical knowledge, there was also social and political decay.

This decline, however, was not sudden nor was it complete, for Egyptian surgery again came to the front during the period of the Alexandrian School many centuries later. During this long interim there is evidence of the continued respect in which medicine was held. Interest in Egyptian physicians was shown by Darius I of Persia in the establishment at Sais around 500 B.C. of what seems to be the first school of medicine under royal patronage. Students were selected, according to Uzahorresenet, the High Priest and "Chief Physician" who organized the school, "from among the sons of men of consequence, no sons of the poor were among them. I placed them under the hand of every wise man. . . . I equipped them with all their needs, with all their instruments which were in the writings according to what was in them aforetime. His Majesty did this because he knew the value of this art, in order to save the life of everyone having sickness. . . ."

That there were physicians in Egypt who were not priests we learn from the Bible in Genesis 50, 2: "Joseph commanded his servants the physicians to embalm his father: and the physicians embalmed Israel." The Bible also gives us a bit of insight into the nature of ancient Hebrew medicine. The ancient Hebrews, for the most part, looked upon disease and accident as punishment by a divine authority because of some previous transgression. As a result, it was only natural for the practice of medicine to be a function of the priests, and such for the most part it was. Under such authority, public health methods could be developed effectively and often were. There was little impetus for progress in surgery, however. That there were other physicians than priests among the Hebrews may be noted in Second Chronicles 16, 12–13: "In the thirty-ninth year of his reign Asa was diseased in his feet, and his disease became severe; yet even in his disease he did not seek the Lord, but sought help from physicians. And Asa slept with his fathers. . . ." It was, however, probably not until after the Alexandrian period that medicine as a separate discipline was studied by the Jews.

GREEK SURGERY AND MEDICINE

Let us now turn to the development of surgery and medicine in Greece. Whether there was any interplay between the Egyptian and early Cretan civilizations insofar as surgery is concerned we have no way of knowing. It is of interest that the god of Greek medicine, Aesculapius, has been considered by some to have been the same as the Egyptian god Imhotep, who apparently actually lived. In the

Homeric poems, Aesculapius is treated not as a god but as an extremely learned and successful physician with two sons, Machaeon and Podalirius, who were both surgeons and soldiers. The Homeric respect for the warrior was matched by equal respect for the surgeon who dressed the wounds. Many of these wounds are described in detail as are the methods for care. They relate in particular to the difference in wounds produced by a sword or spear and those produced by an arrow. The latter wounds were considered less serious, and methods of extracting arrowheads were described.

Following the period of Homer, little of significance occurs in Greek surgery until the advent of the Hippocratic writings. During the sixth and fifth centuries before Christ, there had grown up in Greece numerous temples of health erected to Aesculapius; of the 50 or 60 known to have existed, the most famous were those at Cnidos and Cos. These temples were presided over by priests; and descriptions of their treatment of patients suggest a combination of mysticism, burnt offerings, and baths. In the areas around these temples, medical families would settle, persons who were not priests but who developed their own methods for the care of the sick. There seems to have been little or no competition for patients between these two groups, one limiting itself to prayers and seeking miraculous cures; the other, a lay group, making observations, collecting information, and suggesting logical therapy. Fortunately, the groups at Cnidos and Cos put many of their doctrines into writing. While Cnidos and Cos have often been referred to as "schools," they probably are best thought of as groups of persons, often of the same family, who pursued similar concepts, rather than as true "medical schools." The best-known pupil of Cos was Hippocrates. The collected works of Hippocrates have been translated into English by several authors and are now easily available. Just which of these treatises were written by Hippocrates himself is not known, and speculation as to authorship has been rife since the time of Galen. Since Hippocrates lived during the Golden Age of Greek civilization, it is possible to date several writings as preceding his time. As a matter of fact, "The Oath of Hippocrates" has been considered by some to have been of earlier origin; but since it is so completely in keeping with the ethics of the period, there is no question as to where it belongs.

The Hippocratic contributions to surgery are tremendous. There is not enough space in this chapter to consider them in detail, but it is hoped that the student sometime in his life (the sooner the better) will read them in their entirety. If he does, he will be impressed with an extensive clinical experience, accurately and modestly recorded. Straightforward observations, simple and logical deductions, and humility are seen time and time again. Hippocrates described no miraculous cures, often giving a gloomy prognosis. He apparently wrote, not to impress anyone, but to give a simple and honest statement of what he knew, a refreshing feat among medical writers of all times. Perhaps a majority of his Aphorisms as we view them today are false, many absurd, some even mischievous—such as VII-87, "Those diseases which medicines do not cure, iron (the knife) cures; those which iron cannot cure, fire cures; and those which fire cannot cure, are to be reckoned wholly incurable." On the other hand, his treatment of congenital clubfoot is remarkably modern. Fractures were treated with both splints and a type of rigid bandage. The principle of traction was well recognized in reduction of fractures and dislocations, although the apparatus used was often crude. Examination of the injured part is more clearly described and the lesion more minutely classified than in the Egyptian period of the Old Kingdom. In the treatment of soft tissue injuries, however, the Egyptians' methods, used 2,500 years earlier, do not fare too badly in comparison.

The consideration of the whole patient appears quite clearly in the Hippocratic Corpus. Nowhere is this better seen than in the Book of Prognostics, Number Two:

> He should observe in acute diseases: first, the countenance of the patient, if it be like those of persons in health, and more so, if like itself, for this is the best of all; whereas the most opposite to it is the worst, such as the following: a sharp nose, hollow eyes, collapsed temples; the ears cold, contracted, and their lobes turned out; the

skin about the forehead being rough, distended, and parched; the color of the whole face being green, black, livid, or lead-colored.

As can be seen, there was no effort to separate medicine from surgery. The two developed as a single entity. In this development, one sees inductive reasoning beginning to play a more important part. It is natural that the beginning science of medicine could not escape the effect of contemporary Greek philosophy. Systems of medicine began to develop, and, since the experimental method had not been clearly defined, it was unfortunately difficult to refute some of these systems if they were established on what seemed to be firm, logical grounds. Such was the case with the doctrine of the humors—blood, mucus, yellow bile, and black bile. When the body possessed a proper balance of these humors, there was health. Where there was imbalance, there was sickness. From this a therapy of opposites could develop to counteract such an overbalance; heat, cold, moisture, and dryness were related to these humors and used in such treatment. In its detail this is a false system, and its pursual retarded the development of medicine. In principle its concept is sound, for who today would deny that an imbalance of certain humoral substances that normally exist in the body is not responsible for much disease?

After the time of Hippocrates there is not much of importance in Greek surgery. Aristotle stimulated considerable interest in anatomy, and it is possible that the Socratic attitude toward the dead human body, well expressed in the *Phaedo,* paved the way for human dissection that was soon to appear in Alexandria.

Alexander founded this town on the Mediterranean after his conquest of Egypt and named it for himself. A year or so later he died and, in the division of the empire, one of his generals, Ptolemy Soter, who may have been the half brother of Alexander, became the ruler of Egypt. Although a Macedonian, or perhaps for that reason, Ptolemy had a great intellectual respect for Greek culture and, therefore, at once began the transfer of Greek scholars and Greek books to Alexandria. This was continued by his successors until the library at Alexandria had become a fabulous institution. It contained an estimated 700,000 papyrus rolls, many of them duplicates, it is true. Scholars of the entire world centered here, and from here probably emanated the first editions of Homer, of Hippocrates, of Aristotle, and many others. Actually, this was not just a library in the sense of a repository of books; it was an institution for scholarly study of all sorts. It prospered for many years. It was in its glory for as many years, in fact, as the Ptolemys were the real rulers of Egypt. Here were fused all of the cultures of the past with those that were then present. We can see even traces of the early Egyptian influence. When this library was destroyed by invading armies of Julius Caesar, of Theodosius, and of Caliph Omar, civilization suffered an injury from which it never recovered. Some of the achievements in medicine have been preserved for us by the writings of Celsus, Galen, and Oribasius—but not enough.

Two outstanding scholars were contemporaries, Herophilus and Erasistratus, active around 300 B.C. They began to dissect the human body, and here the study of anatomy had its formal beginning. A number of the names that Herophilus gave to organs still persist—the duodenum, the retina, the dura and pia mater, the prostate, the epididymis, and many others. Unfortunately, there was no great artist such as Leonardo or Kalkar to illustrate these dissections, or if there was, the drawings were lost. It is difficult to perpetuate anatomic studies without the art of illustration, and thus much that was fundamental in anatomic knowledge was not preserved.

Studies were made of normal body functions. The pulse was counted, and the flow of blood through arteries and veins noted. The crystalline lens was removed for the treatment of cataract. Abscess of the liver was operated upon, and the effect of the emotions on the body studied to a high degree. The description of motor and sensory nerves suggested observations on the living. Not only was the human cadaver dissected, but Celsus writes that human vivisection was done on condemned criminals and describes in detail the advantages derived from such a procedure over that of the dissection of the dead body. He also criticizes the practice of such human

vivisection from an ethical standpoint in that but little could be observed that had not already been seen in the badly injured.

ROMAN MEDICINE

Celsus, a well-born Roman, was the author of many scientific works including a detailed summary of medicine. He was not a physician in the sense that he was not a practitioner of medicine. He should be considered primarily a compiler. While he thus contributed nothing new, his style was so clear and succinct that he was widely read by physicians of his period and might be thought of, therefore, as one of the important early medical educators. He was given the title "The Medical Cicero." He held the position of secretary to the Emperor Tiberius and, being an eminent scholar, was able to introduce to the Latin world a description of the best in Alexandrian surgery. Strangely enough, soon after the time of Pliny, his works were rarely referred to, and the *De Re Medicina* manuscript rested undisturbed in the Vatican until it was published in 1478 as one of the earliest of printed books. It is here that we find mandrake and poppy considered in detail as anesthetics, and it is here also that we find described the cardinal signs of inflammation, calor, rubor, tumor, and dolor.

The Romans possessed a strong antipathy to the medicine of a foreign people. For centuries the Hippocratic contributions and the medicine of the Alexandrian school were held in contempt. This is seen clearly in the speeches of Cato and the writings of Pliny. In its place the Romans preferred to adhere to incantations and mysticisms and, as Pliny has stated, were without physicians for 600 years. After the conquests by Pompey and Lucullus, in the first century B.C., many Greeks began to migrate to Rome, and it was not long before their medicine came with them. One of the first physicians in Rome was Aesclepiades, around 90 B.C. He was not the most learned nor the most able, but a beginning was made.

Shortly after the time of Celsus, when Roman medicine was reaching a period of chaos in keeping with the decline in morals and the general social structure of that once powerful empire, there came upon the scene a man whose work was destined to color the development of medicine for almost the next 1,500 years, Claudius Galen (*cir.* 130–200 A.D.). An unusually able clinician, he attracted patients from all parts of the world, among them the Emperor Marcus Aurelius, who considered him the only physician in Rome. His success was no accident. Born in Pergamon in Asia Minor, he first studied medicine at the local Aesculapion and later in Smyrna. By the age of 21, Galen was considered a well-educated physician and already was the author of several textbooks. He was not satisfied with his education, however, and for more than nine years he studied—in Corinth, Phoenecia, Palestine, Crete, and finally in Alexandria. He returned home for a while but at the age of 32 was in practice in Rome. Although a busy practitioner from the beginning, he fought the medical quackery that existed around him with all his power. He brought back decency into the practice of medicine. His ethics approached those of Hippocrates, and his teachings combined the best in pre-Hippocratic and Hippocratic medicine with the most advanced findings from the Alexandrian school. He was not content with this and continued his anatomic and physiologic studies during his active life. Since human dissection had become unpopular, he procured animals—animals of every type, even an elephant and a hippopotamus. His findings were carefully described, and his clinical and experimental writings filled many books. Well over 100 of these books have survived.

The authority of Galen in medicine was so great that none could challenge it successfully for many centuries after his death. This was not because of Galen's perfection but stemmed rather from the astigmatic concepts of clerical scholars that followed him. Although aggressive and self-confident, Galen was never blind to a new observation, and perhaps he himself would have been the first to criticize those later followers who preferred to study his writings rather than to observe natural phenomena.

MEDIEVAL MEDICINE

The Roman world was in an upheaval following the time of Galen, and the social and

cultural turmoil that existed was reflected in more ways than in surgical stagnation. Nevertheless, surgery was a casualty. Thus we find the next 1,000 years less productive. With the exception of an occasional minor introduction that may or may not have been successful, the medical and surgical world followed the principles elaborated by Galen. An example of the type of progress is furnished in the treatise on aneurysms by Antyllus as given by Oribasius. Galen described aneurysms and also recommended the ligature of arteries. Antyllus developed the concept further by recommending the treatment of peripheral aneurysms by ligating both proximal and distal to the swelling without excising the sac.

The Christian Church began to take a firm hold in the Mediterranean area, and the concept of cure of disease by prayer, incantation, and miracle began to hold sway. Disease was caused by sin. Therapy was thus related to the soul and not to the body. Not only was there an edict against anatomic dissection of the human body, but any form of surgery relating to the making of an incision was condemned. The human body could not be mutilated in any way, and a surgical incision was considered mutilation. Strangely enough, this did not apply to phlebotomy. Under such a situation, surgery could not develop. In fact, it rapidly declined in the Christian lands. All medicine, fortunately, did not suffer a similar fate, as can be seen when Benedict Nursia established a monastery, Monte Cassino (*cir.* 529 A.D.), where the care of the sick was one of its functions and where there was an herb garden. As time went on, other such monasteries were to be established to do likewise, and we thus see hospitals beginning to take more definite form. Care of the ill was becoming a function of the Church. Scientific observations and inductive reasoning gave way to kindness, compassion, and herbs. The loss, therefore, was not complete. Furthermore, in these same monasteries, the writings of Hippocrates and Galen were being preserved and laboriously copied.

In the Arab world, surgery was running into similar difficulty. Here again there was a religious ban on dissection of the human body, but it is doubtful if there existed, as some have claimed, specific statements in the Koran barring an incision of the sort made with a knife. Perhaps the considerable development of the cautery under Arab influence played a part. At any rate, much of Arab medicine and surgery resembles that of the Greco-Roman school and was undoubtedly affected by Nestorius and his followers, who had been banished from Jerusalem in 431 A.D. and who aided in the founding of a school at Jundishapur. Two figures stand out pre-eminently in the Arab world, Rhazes (860–932 A.D.) and Avicenna (980–1037 A.D.). Rhazes certainly used the knife, and one whole book in his *Continens* is devoted to surgery. Here he describes, perhaps for the first time, the use of catgut as a ligature and a suture. It was similar to that used for harp strings (kit gut), being made from the submucosa of sheep intestine and not from that of the cat. Much of the surgery followed closely that of Paul of Aegina, who lived in the seventh century in Byzantium and who followed Galen closely.

Avicenna was not a surgeon and probably never even practiced medicine. Yet his writings have been considered as representative of Arabian surgery. The writings of both Rhazes and Avicenna were voluminous and were to affect medicine of the Western World long after other forms of Arab culture had begun to wane. Perhaps the greatest surgical writer of the Arabian school in the West was Albucasis (936–1013 A.D.) of Cordova, but it is difficult to find in any of the Arabian writings any new fundamental principles. On the other hand, these authors were past masters of the aphorism. Furthermore, many of these books were obviously to a large extent compiled, the author of the compilation receiving credit that belonged to previous men. The eminent medievalist, Loren McKinney, has expressed it well:

> Greco-Arab work translated into Latin shortly before 1100 by a monk called Constantine, the African, who probably lived at Salerno for a while but who wrote and died at the monastery of Monte Cassino. For example, the earliest Salernitan surgical work often referred to as "the first modern textbook on surgery," comprised in large measure (about one half) material copied from Book IX of Constantine's *Pantegni* which

in turn had been translated from Book XIX of the *Kitab al Maliki* of Ali ibm Abbas, a tenth century Persian who in turn had borrowed it from Book VI of the *Epitome* of the seventh century Byzantine Greek, Paul of Aegina, who indicated in the prologue of his work that he had appropriated the cream of what others had written, specifically that written by the fourth century Greek, Oribasius, who in turn had drawn so heavily on Galen's work that often he is called the "ape of Galen."

As one can see, the technic of the writing of a textbook of surgery has an ancient history.

It is of interest that Jewish medicine and Jewish physicians achieved considerable prominence in the Arab world. One of these was Moses Maimonides who died in 1204 A.D., mourned by Moslem and Jew alike. As a matter of fact, the Jewish physicians seem to have fared much better among the Moslems than with the Christians, although many of them were employed as court physicians in central Europe by Christian rulers.

The period now appears in which we begin to see for the first time (if one excludes itinerant quacks) a separation of medicine from surgery. Pharmacy was being developed to a high degree and herbal medication was being exploited. In this perhaps Avicenna played a prominent part. There was another event, however, that although at the time it seemed simple and unrelated, was to play an important role in the future of surgery. In 1092 a Papal decree was sent to all monasteries forbidding monks and priests to wear beards. To fulfill this decree required the presence of a barber in monasteries, and, since it had already become the custom in many monasteries for monks to be bled at particular intervals, it was only natural that the same man be required to perform both functions; and so was wed the barber to the surgeon, the Rasor et Minutor—a simple story, probably too simple to be completely true. At any rate, this barber-surgeon was soon performing minor surgical procedures about the monastery and in secular life as well. A union had taken place that was to affect surgical education and practice more profoundly and more adversely than governments or the Church.

Important to surgical development was the attitude of the Church toward the practice of medicine, in particular surgery, by ecclesiastics. Coulton has called attention to the statement at the Councils of Reims (1125) and Lateran (1139) that "men vowed to religion should not touch those things which cannot honorably be mentioned in speech" and the enunciation of the Council of Tours (1163) that "the Church abhorreth bloodshed." While none of these directives prevented the practice of surgery by those who were not ecclesiastics, it so happened that at this period the majority of institutions at which an education could be obtained were operated by the Church. Medicine must necessarily, therefore, become involved in scholasticism that was sterile and unrewarding. Surgery must be practiced by uneducated and too often unethical craftsmen—the barber, the lithotomist, and the herniotomist.

Hope appeared on the horizon. At about this time, there developed at Salerno, just south of Naples and adjacent, the monastery at Monte Cassino, a group that was to have a considerable impact on surgery and eventually to influence university teaching profoundly. There have been questions raised as to whether Salerno was a school in the formal sense, for many who studied there possessed some deficit in the classical knowledge of the period. It was also secular. These two things could easily color contemporary opinion, and this must be remembered when appraising the criticism of Salerno emanating from universities such as that of Paris. There certainly was a definite curriculum. To be admitted, the student must be at least 21 years of age and of proven legitimacy. He must have studied logic for at least three years. The medical curriculum lasted five years with an additional year of preceptorship in practice with an older physician. This was followed by final examinations. There is something modern about all of this, including the decree of Emperor Frederick II that anyone practicing medicine must be examined in public by the teachers at Salerno "in order that the king's subjects should not incur danger through the inexperience of their physicians." This may have been the first place in which medical degrees were formally granted. Here,

also, we find the physician referred to as "doctor" for the first time. Women supposedly taught on the faculty, perhaps the most famous being Trotula, although this has been denied. There apparently was no religious, racial, or national influence to direct the faculty. Here appears academic freedom for the first time. Perhaps the best known of the Salernitan surgeons was Roger, who wrote his famous *Chirurgia* in 1080. Other well-known surgeons who at times attended this school were Roland of Parma (1170–1264) and Hugh of Lucca (d. 1257).

It is difficult to be confident about Salerno. Separating myth from fact at this late date is impossible. Much has been written about the place that is contradictory. It certainly did not resemble too closely some of the later universities of western Europe. This area did serve as a surgical center and played a part in the subsequent development of surgery in some of the other Italian centers. One can even see surgery emerging as a separate discipline. There was preserved a mixture of the Greek and the Arabic surgery; from this nucleus there was to grow a better medicine. Salerno as a school was eventually abolished by Napoleon.

Medical education began to spread northward as other universities became prominent —Montpellier, Bologna, and Padua. Bologna particularly attracts surgical attention. Strong in its faculty of law, it fought and won from the clergy its right of self-government. While there naturally was a school of theology, the attraction of the medical school was great. Here were drawn the young men who had no interest in the sterile jargon of the scholastics and who did not wish to approach medicine as clerics. Many of these students were intellectual rebels seeking an explanation for the natural phenomena they observed.

Outstanding was Hugh of Lucca who, as has been mentioned above, obtained some of his education at Salerno, and his son Theodoric (1205–1298). Among other things, they recognized the possibility and the value of primary healing of wounds. They demonstrated that the previous teachings of Roger and Roland that suppuration and "laudable" pus should be formed in wounds was both unnecessary and dangerous. Anesthetic agents also held their attention. Sponges soaked in opium, mandrake, and similar substances were used to deaden pain.

Another great teacher was William of Saliceto (1210–1277), who brought back into prominence the use of the sharp scalpel and who argued for the unity of medicine and surgery. He had two great pupils, Guido Lanfranchi (d. 1315) and Henri de Mondeville (1260–1320). Lanfranchi was banished from Milan because of political reasons and went to Lyons and later to Paris. While less enthusiastic for the scalpel than was his teacher, he carried surgical education to France, struggling to make it part of the medical teaching at the University of Paris. Later Mondeville also returned to France and became the first Frenchman to write a text of surgery. He was an able surgeon, a good anatomist, and an independent thinker. He once remarked that "God did not exhaust all of his creative power in making Galen." He probably was one of the first to use anatomic illustrations in his lectures. He advocated the use of the ligature, of torsion to vessels to stop bleeding, and of the tourniquet and again championed the value of dry wounds. To him, surgery was a therapeutic arm of general medicine. Where he saw occasion to disagree with scholasticism or even with Aristotle and Galen, he did so. He detested pomposity and his wit was caustic. As a result of these qualities, he was greatly respected and equally feared—and decidedly unpopular with the Faculty of Paris. Succeeding him in surgery in Paris was Guy de Chauliac (1300–1368). To explain Guy let us digress for a moment.

During this period anatomy was beginning to make its appearance as a formal study. Post-mortem examination for legal reasons had gradually come about and along with it the permission for public dissection. Such dissections were not taken lightly, however, for the sanctity of the body was still paramount. As an example may be cited a decree issued at the University of Tübingen that "Every three years the body of a criminal shall be dissected. All who take part shall attend a mass for the subject's soul and shall afterwards attend the remains to the grave." These dissections were not attended by curiosity seekers, but were limited to professional men—physicians, scholars, and students. The

actual dissection was usually done by a helper, the professor sitting on an elevated platform describing what was found or equally often what Galen said should be found. It is obvious that such dissections were perfunctory and contributed all too little to true anatomical understanding. Under the leadership of Mundinus (*cir.* 1275–1326), who taught at Bologna and who had developed considerable civic influence, anatomy became a basic study in the medical curriculum. In the light of our present knowledge or indeed in the light of that of a couple of centuries later than Mundinus, he was not a good anatomist. He was an inaccurate observer, his terminology was a composite of several languages, and he was handicapped by poor illustrations—but he was his own prosector. This professor forgot his dignity, did his own dissections and recorded them. He opened the door to the study of anatomy through which others were to follow, a door which, in spite of many obstacles, has since never been closed. One of his pupils was Guy de Chauliac.

Guy was critical of Mondeville; and whether from jealousy or sincerity, the result was the same. It endeared him to the physicians of Paris. He scorned the early suture of wounds and the ensuing lack of suppuration. To him good wounds must be purulent. The teaching of anatomy by illustration was a subject for ridicule. In spite of all this, Guy was, for his period, a competent observer and an excellent clinician. He was forthright and dogmatic. His *Chirurgia Magna* was to dominate the surgical world until the time of Paré. Here one finds described nicely the treatment of femoral fractures by traction and the use of a rope suspended above the bed of the patient to aid the patient in changing his position. Perhaps it is not too unkind to say, however, that one sees in this book much of the teaching of one of his old professors—Henri de Mondeville.

Slowly a knowledge of surgery spread northward. Prominent in London was an English surgeon, John of Arderne (1306–1390). While most of his education was obtained in Europe, he was a "practical" man, his approach being completely unfettered by the experience of others. His great interest in fistulas led him to the recognition of cancer of the rectum and concerning it he gave the admonition, "Do not be led away and offer to operate. It will be a disgrace to you." He made the diagnosis by digital examination of the rectum. Unfortunately, John is also remembered by the exorbitant fees he charged.

This resurgence of independent thinking on the part of well-educated surgeons, in spite of the handicap of itinerants and barber-surgeons, began to make itself felt throughout Europe. In the thirteenth century a medical school had been established at the University of Paris but, since it was under clerical control, surgery could not be taught. The ban on the practice of surgery did not hold for those clerics who were not active in church affairs, and the Collège de St. Côme had been established in Paris as early as 1160; here surgery was taught. A sort of academic compromise had come about, for Latin was the language used at this school but surgery could be taught and the faculty could be married. It was to this institution that Lanfranchi came in 1295 and Mondeville later. By their time, St. Côme had achieved considerable respectability. Unfortunately, it also tended to become restrictive and its licentiates, who were called "surgeons of the long robe," found themselves at odds not only with the more sophisticated group at the University of Paris but also with the more illiterate barber-surgeons, called "surgeons of the short robe." Most of these latter surgeons knew no Latin and, since texts were not as yet written in the vernacular, had no way of studying the older classical surgery of Mondeville and Guy. This led to confusion throughout France, for there thus existed three different groups of practitioners. Eventually this was to be rectified, but not until after a long struggle.

Although admitting a prejudiced point of view, it seems to this author that the surgery of this period has never received its proper place in its effect on subsequent history. Men like Lanfranchi and Mondeville made themselves outstanding because of their independence of thought. Dogmatic scholasticism found itself competing with virile minds in surgery capable of agnosticism and ready to break with the past. These men were concerned with the interpretation of phenomena, not with metaphysics. Given a printing press, they would become dangerous. It does not seem accidental that the area that nurtured

these minds, Italy, was also to give rise to many others who were to lead western Europe into the Renaissance. Active intellectual ferment does not remain confined.

Leonardo da Vinci (1452–1519) was one of these. He is not considered a surgeon; yet, as was true in many fields, this genius had surgical ideas that were sound. He is supposed to have dissected over 30 bodies, and his accuracy of observation combined with his ability as an artist gave anatomic information not since equaled. Unfortunately, these illustrations were not published until some redrawings appeared in the late eighteenth century, and surgery suffered because of this. Fortunately, excellent copies are now available. Forty years after Leonardo, Vesalius (1514–1564) was to make his great contribution.

Vesalius, a Belgian, studied at Paris under Sylvius and Guinther, the latter in particular giving him great encouragement. He subsequently went to Italy and, in 1537, was appointed professor of surgery and anatomy at Padua. Although a popular lecturer, Vesalius soon began to concentrate on anatomy. He was impressed, during his dissections, with the many errors present in Galen's anatomic concepts just as he was with the physiologic implications of some of his new findings. With another Belgian, Jan Stephan van Kalkar, who had been a pupil of Titian, as the artist, charts of his dissections were made. Six large plates of these dissections were published, his *Tabula Anatomicae*, to be followed by the well-known *De Humani Corporis Fabrica*. He was 29 when this came off the relatively new printing presses at Basel, under his careful inspection. At about the same time the *Epitome* was produced. While first at Padua, Vesalius had translated the *Ninth Book of Rhazes*. While *Fabrica* was being prepared, he participated in the translation of an edition of Galen. In describing previous concepts of this master he could, therefore, speak authoritatively and then prove his point by visual means. The authority of Galen had, at last, been successfully challenged. It remained for William Harvey to give it the final blow. But Vesalius had now become a controversial figure. With the praise for him, there was also bitterness and jealousy toward him. He resigned his chair at Padua to become the physician of Charles V of Spain and, later, of this king's son, Phillip II. Even his success as a clinician in Madrid and as a surgeon in the army aroused envy and intrigue. He also found himself in a country where "not even a skull could be had" for anatomic purposes. He died on a return journey from Jerusalem in 1564, when his ship was wrecked.

Succeeding Vesalius at Padua was Colombo (1510–1599), later Fallopius (1523–1562), followed, in turn, by Fabricius ab Aquapendente (1533–1619), the teacher of William Harvey. In Rome was Eustachius (1520–1574). These men all made great contributions to anatomy and yet, at the same time, they taught and practiced clinical surgery. Of the great anatomists of this period only Michael Servetus (1509–1553), who demonstrated the pulmonary circulation, was not a practitioner of surgery. Knowledge of anatomy was no longer a philosophic adornment, but had become a part of the surgeon's armamentarium. Unfortunately, the ordinary surgeon was not ready to use this knowledge completely. In most respects, clinical surgery had been making slow progress. Although Paracelsus (1493–1541) had made a valiant effort to reintroduce the concept of a clean wound, he had had little success. Paracelsus was not a surgeon. The lithotomists and the herniotomists were ubiquitous, although insofar as the growth of surgery was concerned they were more of a nuisance than a hindrance.

A new development in the progress of mankind made its appearance which also affected surgery: Gunpowder was invented. Wars thus became more frequent and, as has been stated, wars always contribute greatly to surgical knowledge. Wounds were more severe and also more common. Much could be learned; and, during wars, surgeons are important to kings. Surgery was ready once again for dominant leadership.

Leadership appeared in the form of a barber's apprentice, himself a barber-surgeon—Ambroïse Paré (1510–1590). Following his apprenticeship, he went to Paris where he lived for three years in Hôtel Dieu, observing and studying the critically ill. After this, he sought and obtained army service and for the next 30 years engaged in one campaign after another, in the interims residing in Paris. His

formal education was sparse; being unfamiliar with both Greek and Latin, his writings were in the French vernacular of the day. A simple, humble man, unusually sensitive to the suffering of others, he was greatly beloved by his patients and by the common soldiers. His honesty and integrity affected the practice of medicine about him. His shrewd intellect and wise surgical judgment made him a favorite of generals and kings.

Paré's contributions to surgery were those that came from observation, and, while valuable, are as a whole no more impressive than those from men who had had a far lesser effect on surgical advance—Mondeville, for instance. Paré advocated the removal of foreign bodies, adequate drainage of wounds, the arrest of bleeding by ligature rather than by cautery, amputation through sound tissue with ligature of the vessels, and the application of soothing ointments for open wounds and burns. His ointment, however, was puppy's fat, oil of lilies, turpentine, and alcohol. He also felt that all contused wounds should be brought to suppuration, but that in open wounds suppuration was not to be encouraged. Apparently he came independently to the same conclusion as did Gersdorff that gunshot wounds carried no specific poison, as had been taught by De Vigo.

The personality of Paré was obviously impressive. He was surgeon to four kings of France. He was sufficiently admired by Charles IX to be sheltered in the royal chambers the night of the massacre of St. Bartholomew, so loved by the common soldiers that he was carried on their shoulders as they marched triumphantly down the street, and so vehemently disliked by Gourmelen, Dean of the Faculty of Physicians of Paris, that he was forced to reply to some of the criticisms with his delightful book, *Voyages faits en divers lieux*. In this interesting story of some of his earlier experiences, he refers to Gourmelen as "mon petit maître." The influence of this personality, combined with the fact that his books were written in a language the common man could read, aided this great clinician in making a strong impression on the surgery of his time.

In England, surgery was slowly finding itself on sounder footing. Gale, Vicary, Clowes, Banister, Lowe, and others gained prominence, chiefly as military surgeons. Tagliacozzi, in Italy, popularized for a time skin flaps in nasal reconstruction. And there were others.

THE RENAISSANCE

The most important thing taking place during this period, however, was outside of surgery and was to affect it only indirectly at first. That phase of intellectual resurgence known as the Renaissance was gathering momentum. During the year that *De Fabrica* was published, Copernicus presented his revolutionary treatise on astronomy. Soon philosophy was to be given its first rigorous reorganization in centuries by Francis Bacon and by Descartes. The microscope was being perfected, and the giants Galileo and Newton appeared on the scene. In a few brief years, experimental science with objective measurement of phenomena had come about. Many of these men had studied medicine; all were scientists.

In Padua, Fabricius ab Aquapendente, one of the successors to Vesalius in the chair of anatomy and surgery, had as a student William Harvey (1578–1657). Apparently Harvey was impressed with the demonstration by Fabricius of valves in veins and attached to them a function not appreciated by his teacher. This led, following his return to England, to a series of carefully conceived experiments that demonstrated effectively the circulation of the blood. His book, *De Motu Cordis et Sanguinis*, published in 1628, in many respects became one of the most important publications in medicine of all time. Not only did it destroy the last vestige of Galenic beliefs, but it also gave the concept of the body as a dynamic organism in a way not hitherto conceived. Here was the real demonstration of the value of experimentation in medicine. To observation and reflection could now be added experimentation. Medicine became a science in the true sense, and from this time on not only could experience continue to be cumulative but proven fact began to pile on proven fact. The result was indeed revolutionary.

In Italy, Malpighi (1624–1694) demonstrated with an improvised microscope the capillaries and capillary circulation, the layers of the skin, the lymphoid nodules of the

spleen, nerve pathways from the spinal cord to the brain, and the glomeruli of the kidneys. Van Leeuwenhoek (1632–1723), with a better instrument, showed that blood contained a solid component, red cells. He demonstrated striations in muscle and the presence in the scrapings from teeth of "little animals, more numerous than all the people in the Netherlands, and moving about in the most delightful manner." Robert Boyle (1627–1691) and Robert Hooke (1653–1703), his assistant, proved that air was necessary for an animal to sustain life, as well as for combustion, and that the lungs served to provide this function. To Hooke, we are also indebted for the concept of the cell; and, although his ideas in the light of present knowledge were primitive, here we find for the first time the use of the word "cell." The Royal Society was established, and experimentation was the order of the day.

BARBER-SURGEONS

These men and others like them were not clinical surgeons but their careers were to affect surgery deeply. It is impressive, however, how long this was to take. Quackery was rampant. The barbers, untaught and uncontrolled, practiced shaving, haircutting, bleeding, or any type of surgery they wished. Itinerant herniotomists, cataract extractors, and lithotomists roamed from city to city. In Italy, the problem was not so great. As we have seen, there were universities in which a surgeon could obtain a good education, and there were moderately effective laws of licensure. By the mid-seventeenth century the schools at Leiden and Amsterdam began to obtain prominence as centers where anatomy and surgery were being taught well. In France, following Paré, the barbers had been amalgamated with the surgeons and, with the triumph of the physicians, the Collège de St. Côme lost greatly in prestige. Germany was showing progress, but Spain remained in the *doldrums*.

In England in 1462, during the reign of Edward IV, a Barber Surgeons Corporation had been granted a charter which, while elevating the status of the barber-surgeon, was designed to exclude from practice the itinerant, irresponsible practitioner. This was not too effective; and, during the reign of Henry VIII, Thomas Vicary (1495–1562), who was surgeon to the king and a member of the Barber Surgeons Corporation, succeeded in obtaining a royal decree calling for more stringent rules governing the practice of surgery and the privilege of obtaining bodies for anatomical dissection. The barbers were no longer allowed to bleed patients or to do surgery of any kind; in return, the surgeons were no longer allowed to shave people or to cut their hair. However, educational facilities for the surgeon remained of a low quality. This arrangement was to persist in England until 1745 when, particularly as a result of the activities of Cheselden, by an act of Parliament, there was a complete separation of the surgeons from the barbers. Finally in 1800 a charter for the Royal College of Surgeons was issued by George III.

The early eighteenth century saw the popularity of the French schools increasing. Students came from all parts of Europe, not because of the presence of outstanding teachers so much as because the growing facilities for surgical study in Paris exceeded those found elsewhere. There were three schools in Paris where a medical education could be obtained. While the physicians had won a victory over the surgeons some years earlier in Paris, better recognition of surgery soon appeared, due in part to the support of Louis XIV and Louis XV.

Toward the end of the seventeenth century, the surgeon Felix, with great fanfare, had performed successfully an operation for anal fistula on Louis XIV. This led to considerable royal interest in surgery and its state in France at that time. So important was this that one should not be too critical of the way this interest was aroused. Felix was followed by Mareschal (1658–1736), who was not only surgeon to Louis XIV and Louis XV but also surgeon of the Charité Hôpital. His influence on the king was great, and he was largely instrumental in having Louis XV establish several chairs of surgery at St. Côme, greatly to the discomfiture of the Faculty of Medicine at the University of Paris. At this period, de la Peyronie (1678–1747) played an impressive role. A native of Montpellier but educated in Paris, he had one of the most successful surgical practices. He gave generously of his time and money for the better-

formal education was sparse; being unfamiliar with both Greek and Latin, his writings were in the French vernacular of the day. Germany was showing progress, but Spain remained in the doldrums.

In England in 1462, during the reign of Edward IV, a Barber Surgeons Corporation had been granted a charter which, while elevating the status of the barber-surgeon, was designed to exclude from practice the itinerant, irresponsible practitioner. This was not too effective; and, during the reign of Henry VIII, Thomas Vicary (1495–1562), who was surgeon to the king and a member of the Barber Surgeons Corporation, succeeded in obtaining a royal decree calling for more stringent rules governing the practice of surgery and the privilege of obtaining bodies for anatomical dissection. The barbers were no longer allowed to bleed patients or to do surgery of any kind; in return, the surgeons were no longer allowed to shave people or to cut their hair. However, educational facilities for the surgeon remained of a low quality. This arrangement was to persist in England until 1745 when, particularly as a result of the activities of Cheselden, by an act of Parliament, there was a complete separation of the surgeons from the barbers. Finally in 1800 a charter for the Royal College of Surgeons was issued by George III.

The early eighteenth century saw the popularity of the French schools increasing. Students came from all parts of Europe, not because of the presence of outstanding teachers so much as because the growing facilities for surgical study in Paris exceeded those found elsewhere. There were three schools in Paris where a medical education could be obtained. While the physicians had won a victory over the surgeons some years earlier in Paris, better recognition of surgery soon appeared, due in part to the support of Louis XIV and Louis XV.

Toward the end of the seventeenth century, the surgeon Felix, with great fanfare, had performed successfully an operation for anal fistula on Louis XIV. This led to considerable royal interest in surgery and its state in France at that time. So important was this that one should not be too critical of the way this interest was aroused. Felix was followed by Mareschal (1658–1736), who was not only surgeon to Louis XIV and Louis XV but also surgeon of the Charité Hôpital. His influence on the king was great, and he was largely instrumental in having Louis XV establish several chairs of surgery at St. Côme, greatly to the discomfiture of the Faculty of Medicine at the University of Paris. At this period, de la Peyronie (1678–1747) played an impressive role. A native of Montpellier but educated in Paris, he had one of the most successful surgical practices. He gave generously of his time and money for the better-

ment of surgery, and it was largely through his efforts and the work of Mareschal that the Academy of Surgery was established in Paris in 1731. Not content, he succeeded in having an ordinance passed in 1743 that definitely separated the barbers from the surgeons in France and placed surgery in a position of professional dignity. Today de la Peyronie is best remembered as having described a type of painless fibroplasia of the penis.

THE BEGINNING OF MODERN SURGERY

Other outstanding surgeons of the period were Jean Louis Petit (1674–1750), noted for his improvements in the technic of circular amputation, the invention of the screw tourniquet, his operation for hernia, and his studies on the clotting of blood. Although not the first to do so, he is supposed to have performed cholecystotomy. There was Dionis (d. 1718), who was a popular teacher of anatomy and left an excellent account of Frère Jacques, the noted wandering lithotomist. Littré (1658–1726) is well remembered for his work on hernia and as an anatomist. He proposed the operation of colostomy in 1710. This was apparently first performed successfully, however, in 1776 by Pillore, a surgeon in Rouen. Toward the latter part of the century, Desault (1744–1795) was the outstanding teacher in France. His lectures in surgical anatomy were unique and practical. He applied this information to the treatment of fractures and to the improvement of surgical technic to such an extent that students came in crowds to hear him. The sisters in Hôtel Dieu registered a formal complaint because the 200 to 300 strangers, besides the regular students at the hospital, who came to hear his lectures constituted a deterrent to the dressing of wounds and the education of their own students. A colleague of Desault who published a monograph on surgical operations with him was François Chopart (1743–1795), remembered today for the amputation technic that bears his name.

In Germany, surgery had been slow in getting started, owing to the social conditions in this land at the time and to the dearth of educational facilities. One of the early German surgeons who had done much to elevate the standard of practice was Wilhelm Fabry (1560–1634), known also as Fabricius Hildanus. After obtaining an excellent classical education, he spent a number of years acquiring surgical experience in many centers. His writings exhibit sound judgment for the period and prove him to have been an aggressive and able man. Among his other achievements, he apparently was the first to perform a cholecystotomy for the removal of gallstones and have the patient survive, no mean feat in 1618. Following Fabry was Johann Schultes (1595–1645), remembered today chiefly by virtue of an ingenious bandage that he devised—the Scultetus binder. Similar ingenuity was evidenced in the numerous surgical instruments he invented, many of them prototypes of the ones used today.

Dominating the field of German surgery in the eighteenth century was Lorenz Heister (1683–1758), who received most of his education in Holland. He found, upon his return to Germany, that his lectures in Latin were completely unintelligible because few of his students had studied Latin. He was forced, therefore, to change to the German language in his lectures and writings, and, probably as a result of this, his influence immediately was felt throughout western Europe. His book *Chirurgie* (published in 1718) was translated into Latin. Later, the Latin edition was translated into English, and in some centers in England was the standard text in surgery for almost a century. Heister made no dramatic contributions to surgery and is best known today for his demonstration of the small valves in the cystic duct. His writings were simple, sound, and voluminous. In originality of thinking and of work, he was not of the caliber of a contemporary colleague, Albrecht von Haller (1708–1777), who taught at Göttingen. Although he was professor of anatomy and surgery, it is highly probable that von Haller never operated on a single patient. His fields of interest were broad and one encounters his contributions at almost every turn—whether it be inconsequential, as on the vagaries in the occurrence of the right colic artery, or substantial, as on the descent of the testes, which he proved by beautiful anatomic dissections of the fetus. It was this work that led both Pott and the Hunters in England to explain the mechanism of indirect inguinal hernia on the basis of persistence of

the peritoneal sac, an explanation which led to a most vituperative argument over priority that has been reported by Beckman. Each claimed to have originated the concept; neither gave von Haller much credit. Of particular interest is the use of the experimental method by von Haller. Also, because so many students from all over Europe came to study under him, his importance in the development of surgery as a science cannot be overestimated. A successor at Göttingen, August Richter (1742–1812), as well as being a particularly able clinical surgeon, did much to advance the Haller concept of scientific surgery. While one can see the beginning of the tremendous surge forward that surgery was soon to take in Germany in the works of these men, he also notes the conversion of the Friedrich Wilhelm Institute into a medical school for the education of military physicians and surgeons.

In Leiden and Amsterdam during the eighteenth century both medicine and surgery remained at a high level. Outstanding in surgery were Ruysch (1638–1731) and Rau (1668–1719) at Amsterdam and Camper (1722–1789) at Leiden. The great Boerhaave, in internal medicine, was such an imposing figure at this time that perhaps one hears less of the surgery than would ordinarily have been the case.

During this period we can give but little space to the detailed advances being made in surgery, for there is much repetition. Because of frequent wars great attention was given to wounds and fractures, particularly of the extremities; and, with the advent of the dissemination of anatomic knowledge, treatment had been markedly improved. Amputation technics had been perfected and, with more confidence in the ligature, aneurysms were being approached surgically, especially those in the extremity. Injury to the skull, the brain, the spine, and the peripheral nerves and, on rare occasions, even to the abdominal viscera and the chest were now being treated aggressively. The classical fields of the charlatans—hernia, bladder stone, and cataracts—had been taken over and therapy improved. Now, before surgery could expand further, even before it could expect to be perfected better, it was necessary to learn more about the underlying nature of the disease process, and the clinical picture that it produced.

Giovanni Battista Morgagni (1682–1771) at the age of 79 published his monumental *De sedibus et causis morborum per anatomen indagatis*. Symptoms were correlated with the disease process found in particular organs at autopsy; it was not a casual correlation. The most critical scrutiny was exercised by Morgagni, and in his proof he was most demanding. To him, the organ was the basic unit in pathology. While this was to prove too rigid a concept, here was something tangible toward which therapy, both medical and surgical, could be directed. His experience was rich, and there appear to be few diseases that did not come under his scrutiny. In his ultimate effect on medicine Morgagni stands alongside Harvey in the importance of his contributions. From the surgical standpoint this concept of morbid anatomy was to be pursued a bit later in England by John Hunter.

Although Henry VIII had removed the English hospitals from the control of the Church and made them secular institutions, active teaching in these hospitals did not occur until a much later date. In the seventeenth century, anatomic and, later, surgical teaching began in the London hospitals. In 1763, the first surgical lectures were given at the St. Bartholomew's Hospital by Pott (1714–1788) and at St. Thomas' by Cheselden (1688–1752) in 1720. Later, when the medical school began at Guys it united with that at St. Thomas', surgery being taught at the latter and medicine the former. These two men, Cheselden and Pott, did much for British surgery. As we have mentioned earlier, Cheselden exerted great efforts toward obtaining separation from the barbers, and perhaps more credit is due him than to any other surgeon for establishing an educational and intellectual climate in England that would attract good minds to surgery. The clinical acumen of Pott is preserved by the unusually lucid description of several diseases which bear his name. His influence was considerable and he used it for the good of surgery. He wrote with great clarity and apparently his lectures had the same quality. John Hunter (1728–1793) studied under both of these men.

Hunter came down from Scotland to be with his brother William, who was some ten years his senior. William had obtained a good classical education after which he studied medicine. He was a cultured, urbane teacher and was highly respected; his younger brother apparently possessed none of these qualities. John did have, however, intense curiosity, a logical mind, the capacity to work, and considerable self-assurance. While it is true the historical moment in which he lived played a considerable part also, these attributes led to one of the most imposing careers in the history of surgery. And yet there were few single great discoveries, and there is evidence of plagiarism unless one assumes that he rarely read—which is true. For example, we have mentioned the episode of testicular descent and inguinal hernia. Another is the implantation of lead pellets into the shaft of long bones of pups to demonstrate that longitudinal growth took place at the epiphyses. This had been done with chicks a century earlier by Stephen Hale. It was a pretty experiment, though, reminiscent of William Harvey, and its inception represented only one of Hunter's many contributions to the study of bone growth. He was deeply fascinated by midgets and giants, and the story of his acquisition of the skeleton of the Cardiff giant is legendary. He was a great collector of biologic material, his museum comprising not only pathologic specimens, but all varieties of animal life as well. His interest in comparative anatomy was phenomenal. He was in the army from 1761 to 1763, and used much of this experience in his treatise *Blood, Inflammation and Gunshot Wounds*. Some of this early experience was later subjected to animal experimentation. The demonstration of the increase in collateral circulation following ligation of a main artery will serve as an example. Certainly, following his day, surgical teaching could be limited no longer to a knowledge of anatomy. Physiology and pathology were brought into surgery, and experimentation became an essential feature. Much has been written about Hunter—so much that few surgeons are so resistant to history as to have escaped reading about his life; therefore further details may be omitted here.

If a good teacher is known by the careers of his students, Hunter was a good teacher. Outstanding among these students was John Abernethy (1764–1831), who succeeded Pott at St. Bartholomew's. He gave private lectures on anatomy in his home. These became so popular that a lecture room was built for him at St. Bartholomew's. Abernethy maintained the interest of his teacher in arteries and, in 1796, performed the first successful ligation of the external iliac for aneurysm. In 1798, he ligated the common carotid for hemorrhage, again successfully. He demonstrated the regeneration of peripheral nerves following neurectomy and suture. Perhaps his greatest success, however, was as a lecturer, for he had a large following. Other outstanding pupils of Hunter were Henry Cline (1750–1827), surgeon to St. Thomas' Hospital; William Blizard (1743–1835), who founded the medical school at the London Hospital; and Astley Cooper (1768–1841). Like the rest of the men who worked under Hunter, Cooper was interested in aneurysms, ligating the common carotid artery for this lesion in 1805 and the abdominal aorta in 1817. Today he is best remembered for work on the breast.

Edinburgh was also becoming an important surgical center at this time. Alexander Pitcairn, who had studied at Leiden, returned to his home in Edinburgh in 1694 and, after much travail, succeeded in starting a medical school there. There was difficulty in obtaining cadavers for dissection, but, with the help of the surgeon Monteith, permission was obtained for an occasional body for dissection. At this time there was no connection between this school and the University of Edinburgh. In 1719, Alexander Monro (1697–1767), who had studied under Cheselden and Boerhaave, returned to Edinburgh and through the good offices of his father, John Monro, a retired army surgeon, became demonstrator in anatomy to the Surgeon Company. Monro immediately impressed his fellow townsmen with his ability—which was real. Unfortunately, because of gnawing fear of the menace of grave-robbing in order to obtain cadavers, there were many people in the area who looked upon his dissecting room with suspicion. This feeling grew so intense that Monro had his anatomical specimens moved to the University in 1725, to prevent them from being destroyed. From then on, he gave

his lectures at the University of Edinburgh, although it was later that the School of Medicine was started at the University. The venture in Edinburgh was successful, it seems, primarily because the teachers were able. Alexander Monro is a good example. His original contributions to anatomy and surgery were minor, yet his lectures and anatomic demonstrations were excellent.

He was succeeded by his son, Alexander Monro II (1733–1817), who performed even more impressively. He studied anatomy under both William Hunter and Meckel; he described the foramen between the lateral ventricles and the third ventricle. It was also he who recommended thoracentesis. Although consulted by surgeons, he himself did not operate. He had much to do with the growth of Edinburgh as a medical center. Unfortunately, his son Alexander Monro III (1773–1859), who succeeded him, was a less effective person. Nevertheless, he had tenure and thus remained in the chair of anatomy at Edinburgh for 38 years, making a total of 126 years in which a single family controlled a particular professorship. In the beginning at Edinburgh, the professor of anatomy also taught surgery, but in a desultory way. Most of the surgery was performed by general practitioners.

In spite of the place occupied by surgery in the curriculum, Edinburgh was the home of several outstanding surgeons. One of the best known was Benjamin Bell (1749–1806), who was surgeon to the Royal Infirmary and the author of one of the important texts of surgery of the period. John Bell (1765–1820), no relation to Benjamin, was also prominent. John Bell was excluded from a position in the Royal Infirmary as a result of local political maneuvers. Nevertheless, he had one of the largest surgical practices in Edinburgh and, in spite of great difficulties, developed a real reputation as a teacher. He had a younger brother, Charles Bell (1774–1842), who at first assisted him in his anatomic demonstrations. In order to escape much of the bitterness existing in medical circles in Edinburgh, Charles went to London where he eventually was appointed Professor of Anatomy and Surgery at the Royal College of Surgeons of England. He previously had obtained the Windmill Street School of Anatomy formerly owned by the Hunters, had seen service as an army surgeon, and had become associated with the Middlesex Hospital. Charles Bell was an excellent artist and was able to depict his observations in a striking manner. Among other discoveries he demonstrated the difference between motor and sensory nerve filaments and described the particular function of the anterior and posterior spinal nerve roots. Today the student meets him through the respiratory nerve of Bell, which supplies the serratus magnus muscle, and through Bell's palsy, a paralysis of facial muscles supplied by the seventh cranial nerve. Bell's book, *The Nervous System of the Human Body,* was the first real textbook of human neurology. In 1835, the chair of surgery at the University of Edinburgh became vacant and was offered to Bell. He went back to his home at the age of 62 with the remark that while London was a good place to live in, it was not a good place in which to die; he died only a few years later. Mankind is definitely richer because Charles Bell lived—a noble spirit indeed.

Surgery as such hardly existed in America until after the Revolution. Men with special, formal education in surgery were few, for such an education must necessarily have been obtained abroad. Since there were not many who could speak French, most of those who went abroad went to London or Edinburgh. Supposedly the first native American to receive such an education was John Moultrie of South Carolina, who graduated at Edinburgh in 1749. The first medical school in America was started in Philadelphia in 1761; William Shippen, the first professor of surgery, had studied with the Hunters in London and at Edinburgh. In New York, Samuel Bard, who also studied in Edinburgh, succeeded in persuading the trustees of Kings College, later to become Columbia University, to establish a school of medicine in 1768. In Boston, John Warren (1753–1815), also a surgeon, played an important part in the founding of the Harvard Medical School in 1783.

Surgery in America was saved the turmoil of being involved with barbers, the restrictions of ecclesiastical control, and the internecine warfare with physicians. This is, to a great extent, the result of the historic period

in which it developed, and also in part to the influence of Edinburgh, where so many early American teachers were educated. Since most surgeons in Edinburgh also practiced general medicine, the tendency to early specialization in surgery was not to take place in America until a much later date. As we have stated earlier, medicine is a part of a people's culture, and it is not surprising that few early American surgeons were scholars and that they lived around larger centers. At first, American surgery represented a transfer from European centers; later, it assumed a personality of its own. There was a paucity of good libraries of medicine, but there were courage, ingenuity, and self-reliance. Because many times isolated men did not immediately seek publicity for their performances, it has been felt that they were not cognizant of what they had done. Such was probably not entirely true.

Among the surgical figures in the early nineteenth century in America, besides those already mentioned, were: Physick (1768–1837), professor of surgery at the University of Pennsylvania, became an important surgeon for his time. McDowell (1771–1830) of Kentucky, noted chiefly for having performed the first successful ovariotomy in 1809, was also an excellent lithotomist and operated frequently for strangulated hernia. Dudley (1785–1870), professor of surgery at Transylvania, was well known for his operation for bladder stones. J. C. Warren (1778–1856), who performed the surgery when ether was first used at the Massachusetts General Hospital, was well known for his aggressive approach toward the surgery of malignant tumors. John Bard (1716–1799), in 1759, did an abdominal section for ruptured ectopic pregnancy. Deadrick (1773–1858) of Tennessee resected the lower jaw in 1810; McCreery (1783–1826) did the first total resection of the clavicle. Nathan Smith (1762–1829) was one of the leaders in medical education. He performed ovariotomy in 1821, apparently at that time being unfamiliar with the previous operation of McDowell. One of his particularly important contributions was the recognition of localized osteomyelitis in the shaft of long bones and drainage by means of a trephine. Smith founded a medical school at Dartmouth and became professor of medicine and surgery at the newly organized medical school at Yale in 1813.

One of the boldest of early American surgeons was Valentine Mott (1785–1865), a student of Astley Cooper. He held the chair of surgery at Columbia College, retaining this position when Columbia merged with the faculty of the College of Physicians and Surgeons. He was professor of surgery at the new Rutgers Medical School and later professor of surgery at the Medical Department of the University of New York. He attracted world-wide attention in 1818 when he ligated the innominate artery. According to Billings, he "tied the subclavian eight times, the primitive carotid fifty-one times, the carotid twice, the common iliac once, the external iliac six times, the internal iliac twice, the femoral fifty-seven times and the popliteal ten times." He also removed the entire clavicle, the right lower jaw, and amputated at the hip joint. His account of the construction of a wooden retractor at the operating table to displace the intestines for better exposure of the common iliac is a highly dramatic story.

While Paris also was one of the favorite centers for Americans to study, it was frequented perhaps more by those primarily interested in internal medicine. Especially were Americans impressed by the systematic methods of analysis that were being introduced, these methods subsequently being reflected in surgical practice. One of the important early contributors to this system was Bichat (1771–1802), who, while still young, died from septicemia resulting from a wound obtained while dissecting. Bichat carried the concepts of Morgagni from the disease of organs to the pathologic processes involving the tissues that composed the organs. He used neither the microscope nor illustrations, being fearful that they would distort his observations. Here one encounters the correlation of anatomy, physiology, and pathology with symptoms. With the advent of improved methods of physical diagnosis, auscultation, and percussion, the clinical picture could be more accurately described.

P. C. A. Louis (1787–1872) introduced statistical study not only to clinical findings but also to therapy; it was largely due to his efforts that bleeding was thrown into discard.

He paid great attention to a written clinical record. Such was brought to this country by Jackson and introduced at the Massachusetts General Hospital, the hospital records in use today being modified from it only in detail. The indications for surgery and the results of various therapeutic procedures could now be studied from a statistical standpoint.

During the French Revolution and the period of the Napoleonic conquests considerable change occurred in French medical education. The universities were involved in the ensuing chaos, and almost complete reorganization occurred. Military surgery for a time was stressed, one of the outstanding surgeons of this period being Larrey (1766–1842). He introduced the ambulance to transport the injured on the battlefield, considerably lowering mortality. Many of the present principles of military surgery were his contribution, and his writings concerning problems during the African campaign were useful in World War II.

In civilian surgery, Dupuytren (1778–1835) was the outstanding figure until his death. It is difficult to find much good said of this man as a person. He apparently would tolerate no rival, was ruthless in obtaining his own advancement, and was second to none in arrogance. He ruined the careers of many of his more promising students when he felt they were in his way; for example Lembert, who, as Dupuytren's assistant, brought out the principle of serosa-to-serosa healing of wounds of the intestine and devised a suture to bring such healing about. This contribution, which could make intestinal surgery possible, lay fallow for a generation as a result of the scathing attack on it by his professor. Nevertheless, Dupuytren had a tremendous following of students, and his surgical innovations and the character of his clinical care were of a high order. A perusal of his lectures, many of which have been translated into English, reveals a scholarly background, careful observations, and splendid technical proficiency. He was no ordinary surgeon, and, in all probability, he earned the professional esteem in which he was held both in his country and abroad.

There were other well-known surgeons of this period—names that are still familiar—Marjolin, Roux, Lisfranc, and Amussat among them.

SURGICAL ANESTHESIA

From the very beginnings of medicine the problem of pain had been foremost; and also from the very beginning many drugs had been used to relieve this horrible affliction. Some of these substances, such as opium, mandrake, and alcohol, have already been referred to. But these drugs were not adequate for the acute pain produced by surgical maneuvers. Amazingly enough, substances with adequate analgesic action had been available for a long time but would not be accepted by the surgical world. Sulfuric ether had been known since early times; Joseph Priestly isolated nitrous oxide in 1776. Furthermore, the fact that these substances, when inhaled, would produce a disturbance in the conscious state with degrees of analgesia had also been known for many years. Just why they had not been brought into use by the surgeon, when viewed in retrospect, is hard to understand. Raymond Lully in the thirteenth century discovered sulfuric ether in his alchemic laboratory, a white fluid to which he gave the name "white vitriol." Over two centuries later, Paracelsus mixed alcohol with sulfuric acid and condensed the vapors coming from this mixture. He tried the effect of this clear fluid on chickens. He writes: "Of all the extracts of vitriol this particular one is the most important, being stable. Furthermore, it has an agreeable taste, so that even chickens take it gladly, and thereafter fall asleep for a long time, awakening undamaged. In view of the effect of this vitriol, I think it especially noteworthy that its use may be recommended for painful illnesses, and that it will mitigate the disagreeable complications of these." In 1542, a year after Paracelsus had died, an itinerant apothecary's apprentice, Valerius Cordus, who had copied many of the prescriptions of Paracelsus when he served as assistant, sold them all to a committee of learned Nuremberg doctors. There the information on ether remained forgotten, for no one bothered to read about it. Years later, Sir Isaac Newton and Godfrey and Boyle referred to "sweet vitriol." In 1818, Michael Faraday, who had worked with gases in Sir Humphrey Davy's laboratory, wrote, "When

the vapor of ether is mixed with common air and inhaled, it produces effects very similar to those occasioned by nitrous oxide. By the incautious breathing of ether vapor, a man was thrown into a lethargic condition which, with a few interruptions, lasted for thirty hours." A few years earlier Davy had written, "As nitrous oxide in its extensive operation seems capable of destroying pain, it may probably be used with advantage during surgical operations in which no great effusion of blood takes place."

These references to early observations are made here in order to give emphasis to the absurdities of priority and to stress the importance of the proper intellectual milieu in establishing the use of this tremendous gift in the hands of surgeons; yet a bitter controversy over priority has arisen. It is true that Dr. Crawford Long removed a tumor from the neck of James Venable on March 30, 1842, under ether narcosis, although at the time it was not reported in a medical journal. It is also true that W. T. G. Morton anesthetized with ether a patient upon whom Dr. J. C. Warren operated on October 16, 1846, at the Massachusetts General Hospital. It has also been established that Morton, a dentist, had consulted Charles T. Jackson, a chemist, who had suggested the use of sulfuric ether as the anesthetic agent. And it is likewise known that Horace Wells, a Hartford dentist, had used nitrous oxide as an anesthetic agent in extracting teeth in 1844. These were all important contributions and should be so considered. There is enough glory to be divided among all these men without further rancor over priority.

There were other anesthetic agents. In 1831, independently, chloroform was synthesized by Liebig, by Saubeiran, and by an American physician, Dr. Samuel Guthrie, of upstate New York. A few months later it apparently was used by Guthrie as an anesthetic while he reduced a fractured forearm of a young boy. Its introduction as an anesthetic agent in obstetrics by Simpson in Edinburgh in 1847 was rapidly followed by use elsewhere. In 1858, John Snow, perhaps the most important of the early anesthetists, published a monograph *On Chloroform and Other Anesthetics*.

Cocaine was introduced as a local anesthetic by Anrep in 1879. Koller employed it as a topical anesthetic in ophthalmology; and William Halsted showed its great value in blocking conduction in peripheral nerves. Synthetic chemists have now produced many agents that have more or less the same physiologic actions without the danger inherent in the use of cocaine.

The introduction of surgical anesthesia produced a tremendous change in the character of the surgery that could now be performed. Besides the relief of pain, it provided the surgeon with two invaluable tools he did not previously possess—time and muscular relaxation. Procedures not hitherto possible could now be performed with ease. The next paramount need was safety.

SURGERY AND THE BIOLOGICAL SCIENCES

To achieve safety the surgeon once again profited by development in other areas of medicine. The outstanding hazard in surgery was one of wound infection and, like most important biologic problems, its solution required a considerable amount of basic information before it could be reached. Slowly this had been taking place but, with the advent of experimentation in medicine, the pace began to quicken. It is assumed that, before the advent of the antiseptic period, surgeons did not strive for a dry wound or for healing by primary intention. As we have already noted, the early closure of wounds is old, as is the removal of foreign material. It will be recalled that when the ligature came into use, it was quickly seen that the ends of the thread should be long enough to extend out of the wound so that they could be "discharged by nature." Dead space was known to be hazardous and adequate drainage was desirable. As a matter of fact, an aphorism of John Woodall in the early seventeenth century can still be used to advantage, "Packeth not thy wounds too tight." The great value of cleanliness had also been well recognized. It is true that pus was often spoken of as "laudable"—as it is true that many times it actually was. Greatly feared by all surgeons was "wound fever," the hot, red, painful wound associated with a febrile state, often accompanied by delirium. This wound often

killed. When recovery did take place it occurred in one of three ways—resolution, suppuration, or gangrene. Obviously the first was preferable, but when it did not obtain suppuration was sought for. This represented localization of the process and at such times was indeed "laudable." Suppuration was not preferred to primary healing in a clean, surgical wound, however, as has been so often inferred. A clear idea of the treatment of wounds toward the close of the eighteenth century can be easily obtained by reading Benjamin Bell's *A Treatise on the Theory and Management of Ulcers.*

But what was pus, and what was its origin? What was inflammation? These questions needed an answer. The physiologist played an important role in the beginning of their solution. Men were beginning to consider the body as an integrated group of dynamic systems; these same men also taught students who subsequently became surgeons. Two of these teachers, Johannes Müller and Magendie, described the leukocyte as it existed in the blood. Pus was noted to contain leukocytes, but it was also considered to be chiefly a lipid; therefore its significance missed. A better knowledge of cells was necessary before inflammation could be understood.

The concept of the cell as an integral part of tissue is usually attributed to Schleiden and one of Müller's students, Schwann. As we have already seen, this is not exactly true for the concept of cell structure had existed years earlier. The evolution of this knowledge is too involved to detail here. What Schleiden and Schwann did do, however, was to insist that all tissues were composed of cells. They also sparked a controversy leading to Müller's demonstration that malignant tumors were composed of cells and Virchow's contention that the cells served as the basis of all pathologic processes and that all cells were derived from previously existing cells. This view of cellular pathology, to the exclusion of all other processes, has been subject to some modification with the resurgence of the importance of the humoral mechanisms of disease, but perhaps not so much as appears on the surface. The contributions of Virchow, Rokitansky, Cruveilhier, Weigert, Conheim, and others in describing the cellular and vascular processes involved in inflammation developed rapidly and were of the utmost importance to the surgeon.

Sound groundwork was now also being laid for the development of bacteriology. Like the study of cells, the recognition of bacteria did not have a sudden beginning. Leeuwenhoek's little animals had been observed again and again. As the quality of microscopes improved, even efforts at morphologic classification of these organisms had been made. Presenting as a fundamental problem always was the origin of these organisms. Did they generate de novo from inert organic material or was such generative power present only in pre-existing organisms? Was there actual contagion as Semmelweis had contended or did these organisms form in the body from damaged tissue and lymph? It was Louis Pasteur who, in a series of elegantly devised experiments, proved for all time that spontaneous generation of bacteria did not exist. For the surgeon this was of tremendous practical as well as theoretical importance. Pasteur's demonstration that the growth of bacteria in a medium occurred because bacteria either were there in the beginning or were brought in by contaminated atmosphere could be applied to the problem of wounds. This caught the attention of a young surgeon in Scotland, Joseph Lister (1827–1912), who immediately associated this phenomenon with the development of sepsis in wounds.

It was fortunate that Lister had been at Edinburgh for his surgical training for the surgical environment was extraordinary. Surgical education in Edinburgh, both at the University and in the extramural school, was never more brilliant than in those years just preceding him. Three men stand out in particular: Liston, Fergusson, and Syme. Robert Liston (1794–1847), unable to obtain a position on the staff of the Royal Infirmary, operated in patients' homes or in rooms that he could provide. By sheer boldness and skill, and helped by his many writings, he became one of the best-known men of his period. Syme often assisted him but their friendship became strained. When Syme was appointed to the chair of clinical surgery at the University of Edinburgh, Liston, who had also desired the position, left for London to become Professor of Surgery at University College. It was there that he performed the first

major operation under ether anesthesia in England, an amputation through the thigh—an operation that he performed in 28 seconds. Although he made many important contributions to surgery, perhaps it was his technical skill that brought him most fame.

William Fergusson (1808–1877) rivaled Liston in his surgical finesse and, like Liston, he also left Edinburgh for London, to occupy the chair of surgery at King's College. In spite of his speed and his technical prowess, Fergusson had the greatest horror of amputation. Perhaps it was because of his great ability that he was able to advocate successfully more conservatism in surgery—wherever possible, local excision was carried out instead of amputation, bladder stones were crushed instead of open lithotomy being performed, and he improved considerably on the cleft palate operation in use at the time.

James Syme (1799–1870), who became head of clinical surgery at Edinburgh in 1833, was another surgeon of extraordinary capabilities, equal to Liston in boldness and similar to Fergusson in his conservatism. Nothing excited him more in surgery than the opportunity to conserve an extremity rather than to sacrifice it. He used ether anesthesia in 1847 and was one of the first ardent champions of antiseptic surgery. And it was by no means because Joseph Lister, a former pupil, had married his daughter. It can safely be said of Syme that he did not subscribe to the nepotism of the Monros.

Joseph Lister received his medical education in London and, deeply intent on becoming a surgeon, went to Edinburgh in order to work with Syme. In 1860 he transferred to Glasgow, and here much of his work on antisepsis took place. Lister tried several substances for use as an antiseptic, eventually selecting carbolic acid, perhaps as a result of its known effect on sewage. His principles were simple. His contention was that wounds became septic because microorganisms were carried to them from the outside. He therefore instituted a system of cleanliness at the operating table, gentleness to tissue, dressings saturated with phenol placed on the wound to destroy accidental contamination, and, later, even a fine mist of phenol sprayed into the air of the operating room to sterilize the atmosphere. He began these studies in 1865 and in 1867 he published his first two accounts in the *Lancet*—studies that were to revolutionize surgery. Lister was able to think clearly and none of his work was abstruse. He recognized the difficulty, even the improbability at first, of excluding organisms from a wound—the use of an antiseptic was therefore necessary. As better methods of protecting a wound would be devised the antiseptic would decrease in value: a fact he realized. There was thus no difference in the principles of antisepsis and those of asepsis, and the controversy that subsequently developed over the two was silly and fortunately was short-lived.

Lister's ideas received firm support from subsequent studies by others. Robert Koch showed that specific organisms which could be demonstrated as being present in infected wounds produced an inflammatory process that was also different, and methods of culture of these organisms were developed. Lister was able to sterilize the catgut ligature and brought it into general use. In 1871, he adapted the use of a drain of India rubber, first employed for the drainage of an abscess cavity by Chassaignac in 1859. The patient on whom Lister first employed this drain was Queen Victoria. This did much to popularize adequate drainage of infected areas, and the rubber drain soon came into almost universal usage. Lister's mortality from amputations fell from 43 per cent to 15 per cent. Von Bergman and his assistant Schimmelbusch, following the lead of Neuber, adapted steam sterilization to surgery in 1886, and by 1891 a ritual of sterile instruments, dressings, and drapes had been instituted in his operating room. In 1890, Halsted began the use of thin rubber gloves; and in 1900, at the Charing Cross Hospital, Dr. William Hunter first used masks of gauze over the faces of the operating team. Asepsis had come of age.

Lister succeeded Syme at Edinburgh in 1869 and later became professor of surgery at King's College in London, a position he held until his retirement in 1896. The career of Lister is one of the most thrilling in medical history.

During that period in which anesthesia and antisepsis were developing, other fields in medicine were also being explored. In physiology, following Magendie in France was Claude Bernard (1813–1878) and in Ger-

many Karl Ludwig (1816–1895) at Leipzig. The effect of these two men on surgery is so far-reaching that it is difficult to evaluate. They stressed the value of research, research methods, and rigorous discipline in the collection of data. Bernard's *Introduction to Experimental Medicine* is one of the classic contributions to scientific literature and to epistomology. Not only were the investigations of these men of great practical importance, but the effect of their teaching on students was even more so. The gastrointestinal tract, the liver, the pancreas, the brain, and the nervous system became the objects of investigation in both normal and abnormal situations. From these studies, along with the impetus in morphologic pathology stimulated by the German group in particular, a true pathologic physiology began to develop and disease was approached from a dynamic reference. Tumors were now classified and their growth and behavior noted. The life history of a lesion could be anticipated and modification that was obtained as a result of surgery ascertained. So was born a new type of surgery.

The field of surgery was rapidly extended as technical development kept pace with basic introductions. For instance, when embolism, infarction, and thrombosis had been elucidated by Recklinghausen, Virchow, Conheim, and others and studies had been made of the coagulation of blood, vascular surgery could develop. The aggressive attack on varicose veins was well presented by Trendelenberg (1844–1894) who also devised and performed an operation for removal of a clot from the pulmonary artery. Asepsis now made open operation on bone possible, and again Trendelenberg performed open suture of a fracture, first doing this on the patella. Specific fractures were being carefully described, distinction from dislocations being insisted upon, and logical methods of reduction developed. The names of Colles, Malgaigne, Velpeau, Bigelow, Madelung, and Buck stand out. Brodie (1783–1862) demonstrated the clinical picture of acute hematogenous osteomyelitis and the advisability of open drainage in the treatment of this disease.

It is obvious that, until aseptic surgery was well developed, neurosurgery could not become too extensive. Wounds of nervous tissue must of necessity heal by primary intention. In neurosurgery, infection always spells disaster. The effect of trauma was therefore first developed. Gama, in 1830, presented a treatise on head injury in which he had performed experiments demonstrating lines of force following a blow to the head and as a result of this work assumed a microscopic disruption in the continuity of nerve tissue and blood vessels. Cerebral localization was still fragmentary; the clinical recognition of intracerebral hemorrhage haphazard. Following the impetus given by Bell, peripheral nerve lesions were becoming more easily recognized and during this period well-known surgical names—Pirogoff, Dieffenbach, Broca, Lucas-Championière, von Volkman, Keen, and Victor Horsley—began to appear in association with lesions of the nervous system. Keen and Victor Horsley actually belong in what we should consider the present period.

Since anatomic teaching was almost completely in the hands of the surgeons, it was natural that more detailed anatomic attention would be given inguinal and femoral hernia. Also, since surgical speed was no longer as essential, structures previously noted at dissection could be examined more thoroughly at operation. Herniotomy thus gave way to herniorrhaphy. The names of Scarpa, Camper, Colles, Gimbernat, Cooper, and Hesselbach came back into common usage. In 1890, Bassini (1844–1924) presented his method of hernial repair which has become classical.

Thoracic surgery exemplifies nicely the dependence that surgery has upon advances in physiologic knowledge. While Fowler, in 1893, performed a partial thoracoplasty to obliterate dead space left following removal of a tumor of the chest and Delorme, in 1894, recommended pulmonary decortication in certain patients with chronic empyema, thoracic surgery was greatly curtailed in its development until better understanding of intrathoracic pressures came about. This did not receive adequate treatment until the work of Evarts Graham and E. T. Bell in 1918; up to that time the thoughtful surgeon rarely entered a free pleural cavity.

The most spectacular advances were in abdominal surgery. It was not that the abdomen had not been opened previously and various viscera removed, for this had taken

place frequently in the eighteenth century. The mortality was extremely high, however, and most responsible surgeons leaned toward the side of conservatism. The story of appendicitis serves as a good example of the change in approach. Many of the important features relating to appendicitis were well known in the eighteenth century but were not particularly stressed because of therapeutic impotence. The term "iliac passion" for the acute abdominal catastrophe had long gone out of use. In 1839, Addison described the course of appendicitis very well, and appendicular abscess had previously been drained. The pathologic findings developed by Fitz in 1886 were well timed to fit the institution of adequate therapy, and appropriate surgery could then be developed by McBurney and others. This illustrates that rationalization in therapy needs the presence of basic information and co-ordination of this knowledge with new concepts of pathogenesis before effectiveness in therapy can be obtained.

William Beaumont (1785–1853) had demonstrated not only that survival was possible with gastrostomy but had studied on his patient, Alexis St. Martin, many aspects of gastric secretion. His findings were of such practical clinical value that today they are still being referred to. Gastrostomy was performed in 1858 by Forster in London; in 1877, Billroth described the procedure. Resection of the pyloric portion of the stomach was performed by Péan in 1879 and by Rydgier in 1880. These were unsuccessful. A successful resection of the pylorus for cancer was performed by Billroth in 1881. As a matter of fact, that same year Wölfler (1850–1917), a pupil of Billroth, described three cases that Billroth had done and one that he had performed. Wölfler is best remembered for his operation of gastrojejunostomy done in 1881. Gastrointestinal surgery developed so rapidly that it would be difficult as well as inaccurate to portray individual contributions. Three names should be mentioned, however, for these men and their pupils did much—Langenbeck (1810–1887), Billroth (1829–1894), and Kocher (1841–1917). They made many original and daring contributions to surgery. They were great teachers and, through their influence, German surgery dominated during the last part of the nineteenth century. They were good anatomists, they were excellent pathologists, and they were cognizant of the latest in physiology and chemistry and ready to apply these principles to surgery. As histologic studies in morbid anatomy developed, they could make contributions in this field for they saw the early lesion and they knew their subject. The surgery of cancer developed under their tutelage. The consideration of surgery as something beyond an extirpative art and the surgeon as more than a craftsman was never better exhibited. It was this spirit that spread to surgery throughout the world. Surgical journals came into being; surgical societies became commonplace. As achievements accumulated, therefore, those of value were immediately adapted to surgery throughout the world, whether a discovery in physics, as that of x-rays, or whether the adaptation of ideas, as the physiologist Ludwig's notion about the use of salt and sugar solutions parenterally. Such developments really represent the essence of modern surgery and perhaps our story could well end here.

It is trite to say that greater progress has taken place in surgery during the past century than in the previous 50 centuries combined. Nevertheless, it is true. An analysis of the background of this progress brings out, I think, certain salient features worth thoughtful consideration. Perhaps the single factor most important in bringing about this achievement has been the use of controlled observations. Observations alone were not enough. Observations, and even reflections, often led astray. Observation, reflection, and experimentation, however, made surgery a science. It also can be seen, though, that surgery is a science existing in almost an ancillary capacity subservient to contributions from many other scientific disciplines. Until the surgeon learned these other disciplines, casually referred to today as "basic science," he could not develop his experimentation. It seems apparent that the same forces at play in the development of this phase of medicine called surgery are also intimately concerned in the education of a single individual who elects to practice it. If this be true, the surgeon must know the essence of a controlled observation and he must have the fundamental knowledge of biologic and physical processes

by which the human body functions. Without this knowledge he may become a craftsman, even an adept one. He will not be a surgeon.

Another thing seems obvious. Individuals made great contributions, often calling for intellectual and moral effort of a high degree. No great contributions were made by committees or teams. Knowledge as encompassed in a single person made for these great achievements. We must always become disturbed, therefore, when we practice a type of surgery that is not individualistic and that requires "borrowed brains"—an internist and a radiologist to make our diagnoses, a pathologist to interpret our lesions, and a resident staff to take care of our patient after operation.

The surgeon must not only acknowledge his scientific obligations but, in addition, must recognize and accept the social responsibility that they carry. These and other things we learn from the history of surgery.

THE SURGICAL HISTORY AND EXAMINATION

J. Englebert Dunphy

THE SURGICAL HISTORY

Modern surgery is both an applied science and a healing art. The surgeon—equipped with a broad knowledge of anatomy, bacteriology, chemistry, pathology, physiology, and surgical technique—undertakes to correct or ameliorate the abnormalities produced in the human organism by injury or disease. In this sense, he is an engineer. But, in applying his knowledge, the surgeon is ministering to the sick in a very special, positive, and, at times, ritualistic way. In this sense he must accept a role similar to that of minister or priest. It is thrust upon him by the anxious sick who want sympathy and understanding fully as much as they want to be cured. The fundamental dignity of man places an obligation on the surgeon to recognize and fulfill this dual function. The taking of a history and the performance of a physical examination are the first steps towards this accomplishment.

The effective application of whatever scientific knowledge the surgeon possesses is entirely dependent upon the history and the examination of the patient. This is true even in conditions that can be recognized by a single x-ray or laboratory test, because the biologic responses of the human organism to injury or disease are so variable that careful and repeated review of symptoms and physical findings is an essential part of the scientific appraisal upon which treatment depends. For this reason, laboratory tests will always be adjuncts to the history and the physical examination. A scientist at the bedside who cannot apply his knowledge effectively is as bad as a charlatan who has no knowledge to apply. Indeed, he is worse, because the charlatan may at least provide encouragement and sympathy, which are as much a part of good surgical care as is the skillful performance of an operation.

A basically well-grounded medical scientist can become a competent surgeon only if he acquires the clinical skill, acumen, and judgment that comes from extensive experience with the care of patients. He must learn to see, hear, feel, and smell. He must concentrate on knowing the normal in order to recognize the abnormal. He must not allow the slightest detail to escape him and he must see in his patient a frightened, disturbed human being, who often can be made well only if he can be understood and treated with compassion and sympathy as well as with skill.

Taking the History. The objectives of taking the history are threefold. 1. To learn all the facts concerning the patient's present illness and past history and to assemble and record them in an orderly and understandable manner. 2. To measure the patient as an individual, which means learning something about his job, his family, his background, his hopes and ambitions, and the type of person he is. Frequently, the decision to operate or the selection of the type of operation required depends upon this information. 3. To inspire confidence by making the patient realize that the surgeon is interested in him and his health, rather than in his disease or injury.

In taking a history several points are important: It cannot be hurried. Both examiner

and patient must be at ease. It is futile to question in detail the patient who is emotionally upset or in severe pain. In certain emergent situations the initial history may be obtained in a few seconds, i.e., "hit by a car" or "swallowed a pin." Under such circumstances the examination will be similarly curtailed and focused. Particular points with reference to the "emergency examination" are described later.

The Chief Complaint. Usually the principal complaint of a patient with a surgical disease stands out very clearly—pain in the abdomen, bleeding from the bowel, a lump in the breast. At times, however, the patient's interpretation of the meaning of the symptoms may cloud the issue. Thus, he may complain of "kidney trouble" when he has a pain in the loin, or "pain in the breast" when the basic trouble is a fear of cancer. Indeed, a patient may deliberately withhold the chief complaint in the misguided hope that if the physician does not find something wrong in his examination, the symptoms are not serious. Many amusing incidents have been recorded about the patient's chief complaint. Too jaunty an approach, "Well, what's the matter with you?" may elicit the justifiable reply "That's what I have come to find out!" A misinterpretation of the patient's stated chief complaint may set the examiner off on the wrong track, as in the extreme and apocryphal example of the pregnant lady who was sent to the Eye Clinic because she said she had not seen anything for three months.

Present Illness. Once settled upon, the chief complaint is the focal point for eliciting the facts of the present illness. Duration, exact character, mode of onset, related signs and symptoms, disturbances of function in other organs and systems—all of these must be ferreted out, assessed, and placed in their proper perspective. A good history taker must have a bit of Sherlock Holmes or, perhaps better, of Father Brown in him. It is incredible how ingenuous and misleading some patients may be. An old gentleman may deny getting up at night to urinate without divulging the fact that he customarily takes a urinal to bed with him. If a patient is asked if he has seen blood in his stools, he may justifiably reply in the negative, because he has never observed his stools. Such foibles are familiar to every good examiner and are easily avoided.

The importance of a careful analysis of symptoms by history taking cannot be overemphasized. Consider, for example, the difference between knowing that a patient has had "midabdominal and epigastric pain for six hours" and knowing that a patient has had "abdominal pain which began in the epigastrium as a mild intermittent colic, gradually settled in the right lower quadrant of the abdomen and became steady and severe." In the first instance, the examiner can draw no conclusions regarding the significance of the pain. In the second, he has good grounds to be strongly suspicious of suppurative appendicitis. Pain is such a common and revealing surgical complaint that it always merits very careful analysis. When it began, how it began, its exact nature, its severity and its radiation, and its relation to such other symptoms as a desire to urinate or defecate are details which must be precisely elaborated.

Similarly, if the patient has vomited, the details must be determined. How often? How much? Was there nausea? Was it projectile? What was in the vomitus? A loss of blood is such a frightening experience that the patient may exaggerate the amount. Here, there is nothing better than for the surgeon to see the specimen personally. The presence of a tumor or ulcer requires specific analysis for which leading questions may have to be asked. Has the tumor changed or varied in size? Was there an injury? Is it painful?

A history of trauma is so frequent in surgical diseases that it cannot be taken at its face value unless the relation between the inquiry and the complaint is definitely established. Most individuals, particularly in describing the illnesses of children under their care, will connect an injury with the beginning of symptoms since it makes the cause easy for them to understand. The average person cannot believe that disease may start in some spontaneous or occult manner and, hence, searches his memory for some initiating episode. He may implicate any event immediately preceding his illness. Trauma is so common, particularly in children, that its relationship to a specific complaint is often unreliable. On the other hand, serious trauma may be sustained by infants and young chil-

dren without the parents being aware of it.

When there is a history of trauma, it is most important to reconstruct the exact details of the accident. Where was the patient when the accident occurred? How was he thrown and did he lose consciousness? Retrograde amnesia, inability to remember the events just preceding the accident, is a sign of the utmost importance because it indicates some degree of cerebral injury. If a patient can remember all the details of an accident, has not lost consciousness, and has no external injury to the head, it is possible to exclude head injury. On the other hand, retrograde amnesia or transitory loss of consciousness may be the only initial signs of what may prove subsequently to be a serious head injury, particularly one associated with extradural or subdural bleeding.

In penetrating wounds, it is of great importance to know the trajectory of the missile. This may provide conclusive evidence that a particular viscus cannot have been injured, or it may indicate probable damage to an organ which, from a casual study of the wounds of entrance and exit alone, might not be considered as being involved. Many times such details of accidents cannot be obtained, and one must not waste time in fruitless efforts to establish data which are not available, because of the gravity of the injury. In compound fractures, the entire course of therapy may be influenced if the surgeon can determine the time element between injury and entrance to the hospital, the kind and degree of contamination (whether the wound was sustained outdoors in a fertilized field, on a highway, or in a home), and especially whether the clothes of a patient protected the wound or were carried into the wound.

One must not overlook the effect of other diseases in trauma and accident. A history of epilepsy, diabetes, or coronary artery disease may provide crucial data, both as to the reasons for and cause of the accident and to the condition of the patient. There are well documented instances in which diabetic patients have been thought to have serious head injuries or to be inebriated, until it was established that they had neglected to eat after an injection of insulin.

When all the data referable to the present illness have been obtained, they must be set down in an orderly fashion. In doing so, apparently unrelated symptoms may fall into their proper perspective and a clue may be obtained to a specific disease which might otherwise be overlooked. Occasionally, after writing up a history, the examiner will find a detail missing which, if positive, would alter the entire interpretation of the illness. This commonly occurs in the examiner's formative years, and he should never hesitate to return to the bedside to review in detail the nature of one or more of the patient's complaints. Moreover, the exact details of this illness may assume great significance at a later time when the patient re-enters the hospital for treatment of either the same or an unrelated disease.

Family History. The family history provides general information regarding the patient and his family that frequently reveals more of the patient's personality. It is important also with reference to certain specific diseases. Jaundice, polyposis of the colon, diabetes, various pigmentation syndromes, certain abnormalities of the pancreas, and a variety of other conditions may have familial tendencies. The family history may make it evident that other members should be brought into the hospital for study and treatment. Although less important than in the past, a history of infectious diseases, particularly tuberculosis and syphilis, provides important diagnostic clues. Thus, stillbirths and miscarriages occurring without obvious cause may be associated with untreated syphilis.

Past History. The past history of a patient's health is of vital importance for two reasons. First, it may provide an essential clue to the correct diagnosis of the present illness. Thus, an unexplained retroperitoneal mass may be related to a "small, black mole removed from the leg seven years ago," or a "little x-ray treatment for acne" when the patient was a child may be the etiologic factor in recurring carcinoma of the skin. Apart from revealing specific factors of importance in the diagnosis of the present illness, the past history reveals an important view of the whole patient. His tendency to be ill, his reaction to previous disease or injury, and the time of onset of various metabolic or endocrine disorders are vitally important. Thus, it is essential to know how long a patient has had diabetes, what

complications have set in, and what treatment he has received. All of these have a direct bearing on the patient's probable reaction to his present illness and to an operation, should it be found necessary. In many instances, a careful taking of the past history will bring out symptoms of some unrelated systemic disease which requires correction before the presenting complaint can be treated. A classical example is the discovery of prostatic hypertrophy in a patient complaining of a hernia. Carcinoma of the colon is also discovered frequently as the "hidden disease" behind the patient's complaint of a hernia or pain in the incision of an old operation.

The examiner must have a set pattern for eliciting the details of the past history in order to avoid overlooking important points. It is extraordinary how frequently a patient will deny ever having been ill but, on direct questioning, will suddenly recall symptoms or even a specific illness directly related to the present complaint. Lest important details be overlooked, the following routine is recommended:

PAST HISTORY

1. *Previous illnesses:* Childhood diseases, tuberculosis, cancer, jaundice
2. *Previous injuries*
3. *Previous operations*
4. *System review:*
   a. Neurologic: headache, fainting spells, dizziness
   b. Cardiovascular: previous history of cardiac disease, dyspnea on exertion, orthopnea, precordial pain
   c. Gastrointestinal: digestion, bowel habits, melena, constipation, diarrhea
   d. Genitourinary: frequency of urination, dysuria, hematuria, pyelitis
   e. Catamenia: time of onset of periods, duration of flow, intermenstrual bleeding, associated symptoms
   f. Endocrine-metabolic: weight, growth of hair, secondary sex characteristics
5. *Nutritional history*
6. *Psychiatric history*

Space does not permit a detailed analysis of the technics of history taking in each of these various systems and the student is urged to consult textbooks of physical diagnosis for such information. However, because of their direct bearing on surgical problems, two aspects of the past history, the nutritional and the psychiatric, will be discussed in more detail.

Nutritional History. A commonly held belief that the average person will naturally select a well-balanced diet is now thoroughly discredited. Ample studies have shown a disturbing incidence of nutritional deficiencies among those who consider themselves well and among the sick, the percentage of course rises sharply. The reasons are many: personal preferences, ignorance, prejudice, alcoholism, and poverty. Tradition and habit are also frequently responsible for the consumption of an obviously deficient diet. Although most of these deficiencies cannot be recognized by clinical manifestations, the physician can suspect their existence from the history and establish their degree by various chemical methods.

In obtaining a nutritional history, one should determine whether the patient consumes a generous and varied diet or eats sparingly of the same groups of foods. Detailed questions are necessary, for example: Does the patient take a fair amount of good proteins such as milk, meats, and eggs? Are vitamin-containing foods such as fruits and vegetables, milk, butter, and meat consumed regularly? The fact that the patient is of normal or even of excessive weight does not necessarily exclude the possibility of nutritional deficiencies, particularly in vitamins and proteins. In such cases, the normal or high body weight is merely a manifestation either of edema or of large fat deposits. Indeed, there is evidence that an unbalanced diet, heavy in carbohydrates and deficient in proteins and fats, may lead to obesity. On the other hand, a history of a loss of weight indicates tissue loss. This may be of adipose tissue, and less significant than a loss of protein which implies physiological impairment.

Even if the patient has eaten a normal diet and has been well nourished, malnutrition is prone to follow shortly after the onset of many surgical diseases. The existence of such deficiencies may usually be taken for granted if there is a definite loss of weight. A knowledge of the kind of foods which have been omitted may be helpful in determining the nature of a deficiency.

Acute nutritional deficiencies, particularly

with reference to loss of fluid and electrolytes, require specific and detailed attention. Laboratory data, such as the serum levels of sodium and potassium, can be interpreted only in the light of such information, and the serum levels of electrolytes may be quite misleading unless the sequences of the nutritional history are carefully recorded. The interpretation of a lowered serum sodium depends upon knowing whether the patient is suffering from heart disease, whether he has been given a sodium-restricted diet or diuretics, and whether he has had a restricted intake or acute excessive loss of fluids from the body. If there has been vomiting or diarrhea, the character and quantity of the lost fluid provide essential information on which sound estimates of the probable type and extent of electrolyte deficiency can be based. Thus in protracted vomiting, if one knows whether or not the vomitus contains bile, he immediately has some idea of the level of the gastrointestinal tract from which fluid is being lost, a matter that relates directly to the electrolyte composition of the losses.

Early in his career, the surgeon must learn to think in terms of "nutritional balance." The elements exchanged and utilized in daily diet and metabolism—nitrogen, sodium, potassium, and chlorine—as well as caloric energy, are of established importance, and there is increasing evidence that magnesium and other elements will be added to the "balance" list.

A knowledge of the probable concentration of electrolytes in body fluids, particularly under circumstances in which there is a large loss of fluid from the body as in vomiting or an external fistula, is part of good surgical care. It may be necessary to determine the precise concentrations by chemical analysis, but the surgeon should not have to wait for laboratory data before beginning the treatment of a patient who has been vomiting from intestinal obstruction. Knowledge of the level of obstruction and of the concentration of electrolytes in the gastrointestinal fluids above this level provides sufficient information for the institution of immediate therapy. The details of management of such problems and the importance of history taking in their appraisal are more fully presented in chapter 9.

Psychiatric History. A good clinical history is not complete unless it contains information about the patient's personality. Such information may be limited to a word or two, or it may extend to a paragraph or many pages involving some of the most intimate details of the patient's life. This material forms the background for the interpretation of the patient's symptoms. The old-fashioned family doctor knew these facts and was able thereby to achieve excellent therapeutic results in many instances without the benefit of modern technics. It is improper to relegate responsibility for knowledge of these facts to the psychiatrist. Although there are many instances in which psychiatric consultation and advice is essential in the management of patients with surgical diseases, in a majority of instances the surgeon must provide the personal interest and sympathy which every human being requires when ill. Failure to do so is unjustifiable. This concept applies most particularly to patients for whom surgery fails, as in inoperable carcinoma, or to patients in whom surgery produces an abnormality which requires special care and attention. Patients with ulcerative colitis requiring colectomy and a permanent ileostomy fall into this category. Only the surgeon can provide the proper advice, guidance, and sympathy in the handling of an ileostomy. It is unthinkable to refer such a patient to a psychiatrist for help in readjustment to the presence of a gastrointestinal stoma.

There may at times be patients who, because of basic psychiatric difficulties, require additional help in adjustment and for whom only specific psychiatric care will be beneficial, but the majority of surgical patients will do far better if the surgeon himself assumes this responsibility.

THE SURGICAL EXAMINATION

The surgical examination consists of several parts: the physical examination, which may be an elective or an emergency examination; laboratory tests and special examinations; x-ray examination; and follow-up examination. Each of these parts is essential to the whole, and today none can be omitted in the study of a complicated injury or disease. Nor can one part of the examination be substituted for any other. Laboratory and x-ray examinations cannot be accepted in lieu of a

careful physical examination. Each portion of the surgical examination has its own particular role and place.

The extent of each part of the surgical examination obviously varies with the condition under study. This applies to the physical examination, many special steps of which may be omitted. For example, a detailed neurologic examination is not ordinarily required in the appraisal of a patient with acute abdominal pain but, under certain circumstances, it may become a crucial factor because of evidence suggesting a cord tumor simulating acute abdominal disease. Similarly, every patient entering a hospital today should have an x-ray examination of the chest, but the need for more extensive radiologic study depends upon particular indications. When serious errors occur in the care of patients today, they are more frequently related to errors of omission or misinterpretation of physical signs than to misuse or failure to utilize laboratory or x-ray data effectively.

Each part of the surgical examination will be discussed separately and some generalizations *regarding its indications and use will* be made.

Physical Examination. A clear distinction must be made between the elective physical examination, which can be done in an orderly, precise, and detailed fashion, and the emergency examination, which must be restricted to certain steps because of the condition of the patient. The elective examination will be considered first.

A. Elective examination. The elective physical examination of a patient must be complete. The ability to do an elective examination and to know that no step has been inadvertently or deliberately omitted is acquired by careful, repeated performance of the complete physical examination according to a set routine. Such a routine is described in standard texts on physical diagnosis and is often included as part of hospital records. In his early years the student must adhere to some such outline so that he acquires the ability to carry out a complete examination without conscious effort. Only by doing this can he avoid making inexcusable errors of omission.

A second vital feature of the physical examination is that it must be well done. It is useless to go through the process of inspection, palpation, and auscultation unless it is done with infinite care. As he performs the individual steps in the physical examination, the surgeon should have as his objective the detection of normal anatomical structures and the variations which have been produced in them by pathological lesions. He is seeking to detect with his eyes, fingers, and ears the physical alterations produced in the human organism by injury or disease. He cannot do so unless he is thoroughly familiar with the normal. For this reason, there is nothing so valuable, in the surgeon's early years, as the performance of many so-called "negative" physical examinations. If these are performed carefully and conscientiously, with the objective of familiarizing oneself with normal anatomic structures and landmarks, the basic groundwork for the recognition of the slightest abnormality is established.

In the performance of the physical examination, every effort must be made to have the patient comfortable and at ease. This is also an excellent time for the surgeon to learn *more about the type of person he has for a* patient. Specific points in the history may be reviewed even as the patient is being examined. Indeed, at times it relaxes the patient to be able to continue to talk about his troubles at this point. This is particularly true of young adults and children. At the same time, attention should be directed toward the patient's facies for evidence of pain, pallor, jaundice, cyanosis, plethora, and so on.

As one proceeds to the complete physical examination, it is essential that the patient be completely stripped of clothing, but that appropriate draping be provided to allay embarrassment, particularly in female patients.

After assaying the patient's general appearance and habitus, it is a good custom to examine his hands next. Many important diseases are revealed in the hands, among them hyperthyroidism, Raynaud's disease, cirrhosis of the liver, and pulmonary ostearthropathy.

Although temperature, pulse, and respiration are frequently recorded by a nurse or attendant, it is essential that the surgeon feel and appraise the pulse, and, at times, also take the blood pressure.

One now proceeds in an orderly fashion to

the complete physical examination beginning with the head and neck, and proceeding to the extremities in accordance with an established routine. Obviously it is impossible to review here each aspect of this examination but certain features merit brief emphasis. Every local lesion should be appraised in the following order: inspection, detection of alteration of function, palpation, and frequently auscultation.

1. *Inspection.* Since it occasions no pain, inspection is always carried out as the initial step in an examination. As the examiner looks at the lesion, he should consciously ask himself what pathologic changes may account for the noted alteration in color or contour. He should think of the abnormality not as an amorphous mass of human tissue, but as a specific alteration produced by disease in skin, muscle, bone, or blood vessel. As he looks at the base of an ulcer, an image of the probable histologic appearance of the lesion should come into his mind.

At times, minor variations may be detected by comparing symmetric portions of the body, as in the examination of the breast, where a little fullness of one breast may be a lead toward an ill-defined infiltrating tumor. A slight droop of the corner of the mouth in a patient with a tumor in the parotid gland may be the clue to the presence of carcinoma rather than of a mixed tumor. The mere droop of an eyelid may be the telltale sign of an infiltrating carcinoma of the lung with involvement of the cervical sympathetic nerves. The recognition of a disease or an abnormality by precise inspection alone is always an exciting experience. Frequently the information so found can be secured in no other way.

2. *Palpation.* Palpation, if carried out skillfully and gently, furnishes a great deal of information. If improperly done, it may so completely alienate the patient that further examination is impossible. Avoidance of pain is the key to successful palpation, yet the elicitation of tenderness is one of its important objectives. Thus, gentleness is of crucial importance. The manner in which the surgeon first places his hand on the patient sets the stage for success or failure. Roughness will antagonize; gentleness will inspire confidence and assure relaxation and co-operation. During palpation, one should watch the facial expression of the patient closely. It may be possible to divert the patient's attention during the examination so that more accurate and objective reactions can be produced. This is especially the case in the examination of children. When attempting to elicit tenderness, one must palpate with one finger only. Palpation with the entire hand produces too wide an area of pressure to permit a precise localization of the tenderness. This applies to all conditions but is essential in the presence of acute abdominal disease.

3. *Palpation of the acute abdomen.* Palpation of the acute abdomen has three objectives: to detect spasm of the abdominal musculature; to localize areas of tenderness; and to outline and identify, if possible, organs and masses. To distinguish between voluntary and involuntary spasm of the rectus muscles, the flat of the hand should be placed gently on the abdominal wall and kept in contact with it, while gentle pressure is exerted on it with the right hand. A distinct resistance can be felt if there is spasm. If the patient is then asked to take a long breath, voluntary spasm will disappear momentarily whereas involuntary or true spasm will persist. Attention is again directed to the importance of outlining areas of tenderness by means of "one-finger palpation." For the details of abdominal palpation with reference to organs and various tumors, the reader is again referred to other texts.

4. *Alteration of function.* Alteration of function of a part may give important information and, at times, should be elicited as a part of inspection because it may inflict no pain. On the other hand, if there is a question of a local injury it may be better to palpate before asking the patient to move an extremity. Detection of alteration of function is the preferred method for determining the presence or extent of injury to nerves. Limitation of movement may also be caused by fibrosis, ankylosis, muscle spasm, or pain. The extent of the spread of tumors to soft tissue or bone may sometimes be appraised on the basis of the alteration of function which they have produced.

5. *Auscultation.* Auscultation is as important in surgery as it is in medicine and is particularly valuable in the appraisal of abdom-

inal injuries, acute abdominal disease, and postoperative abdominal states. It is also a useful and valuable habit to auscultate swellings and tumors anywhere in the body. It is amazing how frequently a vascular lesion will be first detected on the basis of auscultation rather than palpation.

6. *Examination of the various body orifices.* This is a part of every complete examination. There is now a general acceptance by patient and physician of the need for rectal and pelvic examination. It is curious, however, that there is a continued failure of many examiners to appraise the mouth carefully. Palpation of the floor of the mouth and the tongue is an essential part of the complete study of any lesion within the mouth. It is also vitally necessary in the appraisal of glands in the neck. Because it may cause discomfort to the patient, particularly during palpation of the base of the tongue and tonsillar fossae, it may be properly postponed until the rest of the examination has been completed.

Finally, the use of the ophthalmoscope and the sigmoidoscope is an essential part of a good physical examination. *It is poor medical* practice to order an x-ray of the skull in the appraisal of headache without first having performed an ophthalmoscopic examination. Similarly no patient should be referred to the radiologist for a barium enema who has not first been studied by means of the sigmoidoscope. These examinations should be a regular part of the examiner's armamentarium and should be used with great regularity if not routinely.

B. Emergency examination. The seriously injured or very acutely ill patient requires an approach different from that in the ordinary elective examination. The history must of necessity be curtailed, and in serious injuries may be limited to a phrase such as "struck by a car" although, as mentioned earlier, the details of the accident are most important in studying the extent and character of the injury. The acquisition of this information, however, is often of secondary importance to immediate life-saving measures. Whether the examination is performed on the battlefield, in the hospital, or on the roadside, the general principles are the same.

The first consideration must be: *Is the patient breathing and has he an adequate airway?* If the patient is not breathing, correction of the situation may consist simply of turning him on his side, face down, and pulling out his tongue so that he can breathe. Simple aspiration or wiping of blood or mucus from the mouth may be sufficient. In some situations, emergency endotracheal suction or tracheotomy may be required; in others, artificial respiration may be necessary.

The second consideration, which may take precedence over all others because of its visible presence, is *the serious loss of blood.* It is often evident at a glance that the patient has no respiratory difficulties, but that he is bleeding massively from an extremity. Here, local pressure over the wound or a tourniquet may be required.

Once an adequate airway has been established and massive external bleeding controlled, a rapid survey of the entire patient must be made. The student is referred to textbooks on physical diagnosis for details of this examination, but it must be emphasized that the most serious mistakes have been made where, because of the presence of *an obvious lesion which seemed to account* for the patient's shock, an inadequate and incomplete physical examination was performed. It takes only two or three minutes to carry out a rapid but careful examination of the head, thorax, abdomen, and extremities and to turn the patient gently on his side so that the back can be inspected. Failure to do this survey examination may result in a patient being treated for an obvious fractured hip when in fact, he is also bleeding from a penetrating wound of the buttocks or peritoneum. Tension pneumothorax, cardiac tamponade, and certain open, sucking wounds of the chest are easily overlooked in the face of multiple injuries unless this routine is followed. Once an extent of the injuries has been obtained by this rapid survey technic, attention must be given to the splinting of limbs, the control of pain, and the treatment of shock.

THE LABORATORY EXAMINATION

Inspection of the Urine, Stool, and Vomitus. Simple inspection of the urine, stool, and vomitus by the surgeon is often an important part of the laboratory examination. Much

the complete physical examination beginning with the head and neck, and proceeding to the extremities in accordance with an established routine. Obviously it is impossible to review here each aspect of this examination but certain features merit brief emphasis. Every local lesion should be appraised in the following order: inspection, detection of alteration of function, palpation, and frequently auscultation.

1. *Inspection.* Since it occasions no pain, inspection is always carried out as the initial step in an examination. As the examiner looks at the lesion, he should consciously ask himself what pathologic changes may account for the noted alteration in color or contour. He should think of the abnormality not as an amorphous mass of human tissue, but as a specific alteration produced by disease in skin, muscle, bone, or blood vessel. As he looks at the base of an ulcer, an image of the probable histologic appearance of the lesion should come into his mind.

At times, minor variations may be detected by comparing symmetric portions of the body, as in the examination of the breast, where a little fullness of one breast may be a lead toward an ill-defined infiltrating tumor. A slight droop of the corner of the mouth in a patient with a tumor in the parotid gland may be the clue to the presence of carcinoma rather than of a mixed tumor. The mere droop of an eyelid may be the telltale sign of an infiltrating carcinoma of the lung with involvement of the cervical sympathetic nerves. The recognition of a disease or an abnormality by precise inspection alone is always an exciting experience. Frequently the information so found can be secured in no other way.

2. *Palpation.* Palpation, if carried out skillfully and gently, furnishes a great deal of information. If improperly done, it may so completely alienate the patient that further examination is impossible. Avoidance of pain is the key to successful palpation, yet the elicitation of tenderness is one of its important objectives. Thus, gentleness is of crucial importance. The manner in which the surgeon first places his hand on the patient sets the stage for success or failure. Roughness will antagonize; gentleness will inspire confidence and assure relaxation and co-operation. During palpation, one should watch the facial expression of the patient closely. It may be possible to divert the patient's attention during the examination so that more accurate and objective reactions can be produced. This is especially the case in the examination of children. When attempting to elicit tenderness, one must palpate with one finger only. Palpation with the entire hand produces too wide an area of pressure to permit a precise localization of the tenderness. This applies to all conditions but is essential in the presence of acute abdominal disease.

3. *Palpation of the acute abdomen.* Palpation of the acute abdomen has three objectives: to detect spasm of the abdominal musculature; to localize areas of tenderness; and to outline and identify, if possible, organs and masses. To distinguish between voluntary and involuntary spasm of the rectus muscles, the flat of the hand should be placed gently on the abdominal wall and kept in contact with it, while gentle pressure is exerted on it with the right hand. A distinct resistance can be felt if there is spasm. If the patient is then asked to take a long breath, voluntary spasm will disappear momentarily whereas involuntary or true spasm will persist. Attention is again directed to the importance of outlining areas of tenderness by means of "one-finger palpation." For the details of abdominal palpation with reference to organs and various tumors, the reader is again referred to other texts.

4. *Alteration of function.* Alteration of function of a part may give important information and, at times, should be elicited as a part of inspection because it may inflict no pain. On the other hand, if there is a question of a local injury it may be better to palpate before asking the patient to move an extremity. Detection of alteration of function is the preferred method for determining the presence or extent of injury to nerves. Limitation of movement may also be caused by fibrosis, ankylosis, muscle spasm, or pain. The extent of the spread of tumors to soft tissue or bone may sometimes be appraised on the basis of the alteration of function which they have produced.

5. *Auscultation.* Auscultation is as important in surgery as it is in medicine and is particularly valuable in the appraisal of abdom-

here that ancillary methods of study, such as sigmoidoscopy and gastroscopy, can be used as supplements to x-ray examination.

The final responsibility for the interpretation of data furnished by x-ray rests with the surgeon. In many instances, x-rays must be repeated because they do not fit with the clinical data. At other times, x-rays must be repeated over a period of time in the hope that early suspicious lesions may be detected on subsequent examinations. Finally, there are occasions in which surgery must be done or withheld contrary to an impression given by the roentgenologist.

There are many special technics in radiology such as cholecystograms, intravenous cholangiograms, operative cholangiograms, angiocardiograms, arteriograms, laminographs, the injection of sinuses, and special methods of examination of the bowel such as double contrast enemas. With these, once again, the surgeon must, by constant association with the roentgenologist, understand the indications and limitations of these examinations. For example, he should know that neither cholecystograms nor intravenous cholangiograms are of value in the deeply jaundiced patient and that an intravenous pyelogram or an intravenous cholangiogram is not a satisfactory measure of renal or gallbladder function. The innumerable situations which may lead to nonfilling of the gallbladder in cholangiography must be known to the surgeon. Frequently, this information is not supplied to the roentgenologist and he may erroneously report a nonfunctioning gallbladder as pathologic.

Good patient care cannot be accomplished by simply referring the patient with a request for a specific examination to the roentgenologist. Repeated consultation and joint review of films and the associated clinical circumstances are prerequisites to good x-ray diagnosis.

SURGICAL PATHOLOGY

Examination of tissues removed at operation or removed by special biopsy technics and study of smears for cellular changes provide important information upon which surgical therapy is based. Many times, histologic diagnosis must be in the possession of the surgeon before he can make a final decision regarding therapy or prognosis. Frequently important decisions also rest upon the ability of the surgeon to identify lesions by gross examination at the operating table. On some occasions, as in breast tumors, the surgeon must make his decision on the basis of a section of the tumor which is frozen and studied by immediate microscopic analysis.

A sound training in surgical pathology is part of a modern surgeon's education. He must continually improve himself by a study of the surgical pathology in each case in which he is involved.

On the other hand, too much weight can be placed upon the pathologist's interpretation of histologic findings. If the pathologist is not furnished with all the details of a case, an erroneous interpretation may be returned. For example, a juvenile mole may be histologically interpreted as a malignant mole. The responsibility for avoiding such errors rests entirely with the surgeon. He must be aware of the fact that there is not a close correlation between the biologic behavior of neoplasms and their histologic appearance. Such correlations can be made only in a very broad way by the pathologist. The final decision as to whether a specific tumor should be treated by x-ray, surgery, or a combination of both rests with the surgeon. For this reason, no surgeon should undertake the treatment of cancer who has not familiarized himself with all the implications of surgical and tumor pathology.

The surgeon should study the microscopic features of each specimen he has removed in order to correlate them with the gross appearance and with the rest of the clinical picture. This is particularly vital in his early years because only in this way can he bring to his work all the knowledge necessary to raise his professional proficiency to its highest plane. It is largely because of these considerations that many of the surgical diseases discussed subsequently will be illustrated by photographs in which gross specimens as well as photomicrographs show the important features of their surgical pathology.

FOLLOW-UP EXAMINATIONS

The high percentage of excellent results following most surgical therapy at the present

significant data may be obtained in this manner which may be overlooked if the specimen is sent only to the laboratory. The character, color, and amount of vomitus are often recorded inaccurately, but if a specimen is saved and the surgeon himself inspects it, precise information is obtained. Similarly with sputum. The specimen should be preserved as well as sent to the laboratory for study. The well-trained, skillful surgeon may detect, in various excretions or discharges, signs overlooked by a laboratory technician. For example, the detection of sulfur granules in the discharge from a chronic sinus may be the key to the presence of actinomycosis.

Whenever the surgeon performs a rectal examination he should inspect the stool removed on the examining finger and place a bit on filter paper to examine for occult blood. More and more this is becoming a routine procedure in surgeons' offices and in hospital wards and is proving an important clue to the early detection of asymptomatic carcinoma of the bowel.

It is frequently stated today that the importance of laboratory tests is overemphasized. This is fallacious. There can be no overemphasis of the importance of laboratory tests because they are crucial and vital to the recognition of certain diseases and in the careful daily appraisal and correction of others. There is all too frequently, however, a great misuse of laboratory tests. Merely because the proper facilities are available is no reason why every patient should have daily sodium and potassium determinations of the blood. On the other hand, the surgeon must be familiar with the minimal requirements and with the need for and meaning of certain tests when they are indicated.

Every patient undergoing a surgical operation should have a complete examination of the urine and blood. In older patients, it is wise to obtain a routine blood urea nitrogen or nonprotein nitrogen. Azotemia commonly accompanies a variety of surgical conditions without revealing its extent by specific signs or symptoms. Moreover, some patients with chronic pyelonephritis will have varying degrees of nitrogen retention without proteinuria.

Special laboratory studies are essential in the appraisal of specific conditions such as the differential diagnosis of jaundice or hypertension, the fluid and electrolyte requirements in patients with diarrhea and vomiting, or the appraisal of diabetes. Many specific tests and examinations may be required, including the determination of the basal metabolic rate, the rate of uptake and the distribution of radioactive iodine by the thyroid gland, and studies of pulmonary functions. The surgeon cannot be regarded as properly trained and equipped to deal with major surgical conditions unless he is qualified to interpret the results of these examinations. It is a mistake to rely on a research colleague or a medical consultant for regular guidance and interpretation of laboratory data. There are many instances in which consultation will be required, but the management of the patient from the point of view of surgical care is the responsibility of the surgeon and cannot be delegated. He is the only one who is able to interpret the meaning of laboratory tests in the light of other features of the case, particularly physical signs.

Special Examinations. In surgical patients, there are many special examinations with which the surgeon must be familiar and of which he must understand the use and application. Cystoscopy, esophagoscopy, gastroscopy, and bronchoscopy are but a few examples of procedures to which every patient need not be subjected but which, when indicated, provide information of great importance.

X-ray Examination. Modern surgery is so dependent upon x-ray examinations that very close rapport must exist between surgeon and radiologist. It is a common error, however, to attach too much significance and precision to x-ray examinations. This applies particularly to studies of the gastrointestinal tract, in which even the best radiologist is working at a considerable disadvantage when he attempts to demonstrate small polypoid lesions or minute craters in the mucosal surface of the stomach, small bowel, or colon. It should be clearly understood, therefore, that negative x-ray reports do not provide assurance of a normal gastrointestinal tract. Conversely, even the best of roentgenologists will occasionally find apparent filling defects in the stomach and the rectum where the diameter of the gastrointestinal tract is largest and the most difficult to examine. Fortunately, it is

3

LABORATORY AIDS IN SURGERY

OSCAR CREECH, JR., AND EDWARD T. KREMENTZ

The mature surgeon has a three-dimensional concept of disease which is evolved from the combination of symptoms, physical signs, and findings at operation. Often this results in a better understanding of the relationship between clinical manifestations and pathologic processes than that of his nonsurgical colleagues. Because of this advantage, surgeons were once somewhat contemptuous of laboratory aids and in fact were often skeptical of diagnoses based primarily upon the results of laboratory tests.

The remarkable developments in surgery during the past quarter of a century came about in part as a result of increased interest in physiologic and anatomic changes resulting from disease on the one hand and its surgical treatment on the other.

The surgeon has learned to use the laboratory effectively, and has come to rely upon it as an aid in diagnosis and a guide to both proper preoperative preparation and postoperative management of the surgical patient. The precision with which fluids and electrolytes may be measured and regulated in the patient following operation is a striking example of the importance of physiology. If surgery is to continue to grow and retain its traditional vigor, it must make use of all available tools both for diagnosis and for definition of changes in function. New technics and methods must be carefully evaluated as they appear, for the research methods of today may become practical laboratory aids tomorrow.

This chapter is designed to acquaint the reader with some of the laboratory procedures which may be clinically useful to the surgeon and is intended to supplement the chapters devoted to surgical diseases of individual systems. Routine laboratory tests have not been included and details of the various technics have not been described since these are outside the province of this text.

CARDIOVASCULAR SYSTEM

In no other area are laboratory studies so essential to the correct diagnosis and precise definition of disease as in the field of cardiovascular surgery. Indications for operation and the type of surgical procedure employed must be based upon an accurate knowledge of the cardiovascular condition. As a result of intense interest in this field during the past two decades, a number of tests have emerged from the research laboratory to become useful clinically. These laboratory procedures are described below.

Cardiac Catheterization. Localization of congenital cardiac lesions and measurement of the physiologic alterations produced by both congenital and acquired conditions are dependent upon cardiac catheterization. This procedure consists in passing a small, radiopaque catheter into an arm vein and progressively through the innominate vein, superior vena cava (SVC), right atrium (RA), right ventricle (RV), main pulmonary artery (MPA), right or left pulmonary arterial branch (RPA or LPA), and finally into a distal branch of the pulmonary artery, until

time owes much to systematic follow-up studies in many clinics where patients are examined for months and years at regular intervals after they leave the hospital. In this way only can the end results of surgical procedures be evaluated; for instance, the recurrence rate following herniotomy with various technics is accurately determined only in this manner. Such examinations are not only appreciated by the patients themselves but also serve a useful purpose in the education of students and younger surgeons. Follow-up examinations are especially important in malignant disease in order to determine as early as possible the existence or nonexistence of recurrent growths or metastases.

Oxygen content of right ventricular blood =

$$\frac{110 \times 100}{14.01 - 12.80} = 9.09 \text{ liters per minute}$$

Similar calculations using minute oxygen consumption and oxygen content of mixed venous blood (right atrium) and a systemic artery are employed for estimation of systemic blood flow as follows:

$$\frac{110 \times 100}{14.01 - 8.45} = 1.97 \text{ liters per minute}$$

Subtraction of the systemic from the pulmonary flow gives the amount of blood shunted through the ventricular septal defect per minute.

In a similar manner, right-to-left shunts may be calculated although it is necessary to assume an oxygen content of 96 per cent of capacity for arterial blood since the peripheral arterial blood has a lower oxygen saturation due to mixing at the ventricular level.

Recently, technics have been developed for catheterization of the left heart chambers. At present, the most effective and safest method consists in inserting a No. 17 needle through the anterior wall of the left main bronchus, under bronchoscopic control, into the left atrium. This technic affords information relative to function of the left heart chambers and the mitral and aortic valves.

Angiocardiography. In some instances, clinical examination, routine roentgenography, and cardiac catheterization will disclose the presence of a cardiovascular lesion but its exact location remains in doubt. Under these circumstances, injection of a radiopaque substance into the cardiac chambers, or into the great vessels as they arise from the heart, may provide the desired information. Angiocardiography can be performed by the rapid injection of about 50 ml. of a radiopaque substance (70 per cent Diodrast or Urokon, 50 per cent Hypaque) into an antecubital vein. Serial roentgenograms of the heart and great vessels are made at frequent (one-half to one second) intervals, thus recording the passage of the contrast material through the heart chambers. Recently, biplane roentgenography and cinefluorography have greatly increased the accuracy of angiocardiographic procedures. In both of these procedures the contrast material is injected, usually through a cardiac catheter, into one of the heart chambers. With the biplane technic, roentgenograms are made in two planes simultaneously at a rapid rate; in cinefluorography the movement of the contrast material through the heart and into the great vessels is recorded on motion-picture film at 24 to 64 frames per second.

Arteriography. Although aneurysms about the aortic arch may be satisfactorily visualized by angiocardiographic technics, lesions of the remainder of the aorta and peripheral arteries require injection of the contrast medium directly into the artery. Visualization of the abdominal aorta and its branches is best accomplished by lumbar aortography. This procedure is usually performed under local or light general anesthesia with the patient in a prone position. A special No. 18 needle is inserted beneath the left twelfth rib about 2 to 3 inches from the mid-line and passed medially and upward through the posterior aortic wall. Contrast material is injected rapidly into the aorta and, at the end of the injection, a roentgenogram is made. By properly timing exposure of the film, the celiac, superior mesenteric, and renal arteries above, and the iliac arteries below may be visualized as they arise from the aorta. Visualization of the arteries of the lower extremities may be accomplished at the same time by exposure of a film placed beneath the thighs and knees immediately after exposure of the film beneath the abdomen is completed.

When the arterial disease is confined to the femoral or popliteal arteries, aortography is generally not necessary and femoral arteriograms should be obtained. The technic consists in the retrograde insertion of a No. 18 spinal needle into the femoral artery at the groin under local anesthesia. Contrast material (15 ml. of 35 per cent Urokon or 50 per cent Hypaque) is injected rapidly and a film beneath the thighs and the knees is exposed at the end of or a few seconds after injection.

Blood Volume. The importance of the blood volume has been recognized by surgeons for many years. The vital role of blood volume in the production and correction of traumatic shock and its importance both to the proper preparation of the patient for

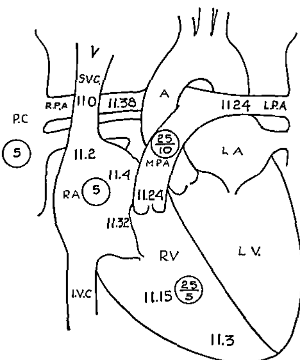

Fig. 1. Diagram of the heart and great vessels showing normal pressures and oxygen contents measured during right heart catheterization. The circled values represent pressure in millimeters of mercury; the uncircled values represent oxygen content in volumes per cent.

the catheter can be passed no farther (pulmonary capillary) (PC) (Fig. 1). Pressures are recorded and blood samples for oxygen content are obtained as the catheter is withdrawn from each of the areas listed. Simultaneously, samples of blood are drawn from a peripheral artery. In addition, minute oxygen consumption is measured. From these data the presence of cardiac shunts may be established (Table 1). The common lesions which permit mixing of blood between the right and left chambers of the heart, or the pulmonary artery and aorta, are atrial and ventricular septal defects and the patent ductus arteriosus. The existence of a left-to-right (noncyanotic) shunt is indicated by the presence of arterialized blood in the atrium, ventricle, or pulmonary artery and a pressure gradient between the systemic and the pulmonary circulation. A right-to-left shunt (cyanotic) is suggested by a significant reduction in peripheral arterial oxygen saturation and equal pressures in the right ventricle and a systemic artery. Frequently, an atrial or ventricular septal defect, or a patent ductus arteriosus, may be demonstrated by passing the cardiac catheter through the abnormal aperture.

Of equal importance with the detection of these congenital conditions are the physiologic alterations resulting from their presence. Measurement of the amount of blood flowing through the shunt may be determined from the arteriovenous oxygen difference and minute oxygen consumption. Thus, the quantity of blood passing through a ventricular septal defect is calculated as follows:

Minute oxygen consumption = 110 ml. per minute
Oxygen content of arterial blood = 14.01 volumes per cent

as a result of conditions affecting the air passages or *restrictive* as a result of conditions involving the chest bellows or distensibility of the lungs. There are three measurements of ventilatory function commonly employed: The *timed vital capacity* consists in recording the maximal speed of performance of a vital capacity expiration. This is perhaps the simplest method of measuring maximum ventilatory performance. The *maximum breathing capacity*, as generally performed, consists in measurement of the maximum, voluntary, minute ventilation. For this test the patient selects his own rate and depth of breathing and this maximum voluntary effort is recorded on a spirometer for either 15 or 30 seconds. *Breathing reserve* is the difference between ventilation at ordinary levels and the maximum breathing capacity. This should represent about 65 to 70 per cent of the maximum breathing capacity; below this level dyspnea is usually evident (Table 3).

Respiratory Gas Exchange. For clinical purposes, studies of lung volumes and ventilatory functions are generally adequate to assess pulmonary function. The phenomena related to the exchange of gas within the lung are exceedingly complex, and, for this reason, studies of these functions have been confined to the research laboratory *until recently*. However, relatively simple methods are available now for clinical study. These include:

1. Measurement—at rest and during exercise—of ventilation, carbon dioxide output and oxygen uptake, oxygen saturation, and carbon dioxide tension in the arterial blood. From these determinations diffusion of gases across the alveolar-capillary membrane may be assessed.

2. The extent to which gases mix in the lung may also be measured by determining the amount of nitrogen in the expired air after the subject has breathed pure oxygen.

Differential Studies. In evaluating thoracic surgical patients with limited pulmonary reserve, it may be necessary to know how total pulmonary function is distributed between the two lungs. For this purpose differential bronchospirometry is useful. This procedure consists in inserting a catheter into the right main bronchus. A balloon is inflated to occlude the right bronchus, thus separating the left lung from the right. By this technic, ventilation, vital capacity, and oxygen consumption of each lung can be measured separately and the functional contribution of each lung expressed as a percentage of the total.

It must be kept in mind that pulmonary function tests are most useful when evaluated in terms of clinical manifestations and roentgenographic studies. Nor do they necessarily indicate or contraindicate the need for operation. Rather, they constitute additional evidence upon which the surgeon can base his decisions regarding treatment.

GENERAL METABOLIC

The problems of water, electrolyte, and acid-base balance are legion in clinical medicine and it is not within the scope of this section to describe the various related laboratory tests and their interpretation in other than a most limited manner. Patients with abnormal intake and output of water and electrolytes as well as those with such internal

TABLE 3. Predicted Normal Values for Vital Capacity and Maximum Breathing Capacity.

Measurement	Predicted Values
Vital capacity, supine, ml.:	
Males	27.63—(0.112 × age in years) × height in centimeters
Females	21.78—(0.101 × age in years) × height in centimeters
Maximum breathing capacity, standing, liters per min:	
Males	86.5 —(0.522 × age in years) × body surface in square meters
Females	71.3 —(0.474 × age in years) × body surface in square meters
Timed vital capacity (males and females):	
First second	83 % of vital capacity
Second second	94 % of vital capacity
Third second	97 % of vital capacity

TABLE 2. Blood Volumes in Normal Male and Female Subjects (Berlin).

Subjects	No. of Cases	Blood Volume ml./kg.	Total Red Cell Volume ml./kg.	Plasma Volume ml./kg.	Hematocrit Per Cent
Males	71	69.0	29.9	38.7	43.0
Females	16	64.4	27.0	37.0	42.0

operation and to convalescence are now well understood. Generally, the experienced surgeon will recognize acute blood volume deficits by the clinical manifestations of tachycardia, hypotension, pallor, and sensitivity to postural change. However, following operations in which blood loss and blood replacement have been extensive it is difficult if not impossible to estimate accurately the status of the blood volume by clinical signs alone. This is particularly true after operations for massive gastrointestinal hemorrhage and after certain thoracic and cardiovascular procedures. Under these and other circumstances measurement of blood volume is desirable (Table 2).

This is accomplished by injecting intravenously a known quantity of a substance which remains essentially within the plasma, allowing it to mix homogenously, and then determining the quantity of this material in the plasma. Three substances are commonly employed for this purpose: T-1824 or Evans Blue Dye, human serum albumin labeled with radioiodine, and erythrocytes labeled with chromium, phosphorus, or iron. When T-1824 or iodoalbumin is used, the total plasma volume is measured and from the hematocrit value the total blood volume is determined. If labeled erythrocytes are employed, the red cell volume is measured and the total volume is then derived from the hematocrit value.

RESPIRATORY SYSTEM

Evaluation of pulmonary function is necessary for any patient undergoing a thoracic surgical procedure and for patients with pulmonary disease, irrespective of the type of operation contemplated. In most instances, a careful history and physical examination, together with a comparison of ventilatory effort at rest and at exercise, will be sufficient. On the other hand, some patients, particularly those with questionable pulmonary reserve, must be studied more thoroughly. Under these circumstances the following measurements of pulmonary function will be useful.

Lung Volumes. There are four components of lung volume which may be measured separately. *Tidal volume* is the volume of gas displaced with each breath. *Inspiratory reserve volume* is the volume of gas that can be inhaled by a maximum inspiratory effort after the inspiratory limits of the tidal volume has been reached. *Expiratory reserve volume* is the volume of gas that can be exhaled by maximum expiratory effort after the expiratory limit of the tidal volume has been reached. *Residual volume* represents the volume of gas remaining after forceful expiration. The sum of these four measurements represents total lung capacity (Fig. 2).

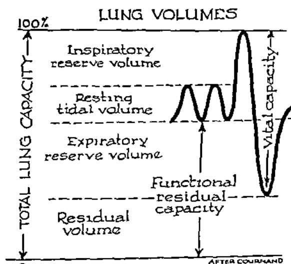

Fig. 2. Normal spirogram showing the various components of lung volume.

Ventilatory Function. The measurement of lung volumes is helpful in evaluating the functional effects of abnormalities of the lungs, while the ventilatory tests assess the functional capacity of the thoracic bellows or the distensibility of the pulmonary parenchyma and the patency of the air passages. Ventilatory dysfunction may be *obstructive*

after 15- or 30-minute intervals. Other methods of gastric stimulation may be used, such as the Ewald or Boas test meal. Another type of test meal is the use of 100 ml. of 7 per cent alcohol injected through the tube. Specimens are taken 30 minutes and one hour after test meals. The most informative type of gastric acidity curve is obtained when the samples are taken at 15-minute intervals for two hours. Maximum stimulation of gastric secretion, which may be obtained with administration of insulin, is useful in evaluating the completeness of vagotomy. An appropriate dose of insulin (10 to 20 units) is given intravenously to produce hypoglycemia of 50 mg. per cent or less. Gastric samples are collected at 15-minute intervals for two hours and blood samples are taken at 30-minute intervals to determine if a satisfactory hypoglycemia has been obtained. The effect of hypoglycemia is mediated through the vagus center in the midbrain and through the vagus nerve. The production of free hydrochloric acid in the stomach, in response to hypoglycemia, depends on the normal reflex arc, midbrain, vagus nerve, and stomach glands. Complete interruption of the vagus nerve will prevent the secretion of free acid. However, the acid-secreting glands still will respond to histamine or caffeine stimulation following vagotomy.

A number of valuable observations may be made from the examination of gastric fluid. The volume of the fasting specimen usually varies between 30 and 60 ml. The presence of more than 100 ml. of gastric juice is usually considered to be evidence of pyloric obstruction. The color of the fluid may denote the presence of bile, which indicates that the patient does not have a complete pyloric obstruction. The presence of blood, confirmed by guaiac or benzidine tests, suggests the possibility of ulcer, carcinoma, or gastritis. Food particles in the fasting specimen suggest obstruction and, if identified and related to time of ingestion, the specific period of stasis can be recorded. Other observations such as the odor and the presence of mucus or saliva should also be noted. Microscopic examination of the residue from a fasting stomach may reveal various types of food particles, blood or pus cells, or various types of bacteria. Occasionally seen are the Boas-Oppler bacilli which are very large gram-negative, non-spore-bearing organisms. Growing in chains and masses they produce lactic acid, and may be cultivated on media in rich milk or in blood. The Boas-Oppler bacilli in the absence of hydrochloric acid and in the presence of stasis may accompany gastric cancer. Sarcinae may occur with stasis in the presence of hydrochloric acid and suggest pyloric obstruction. Occasionally parasites may be found.

The presence of free HCl and total acid in the gastric secretion is important. Usually these observations are made on quantitative bases and expressed in degrees of acidity, the degrees indicated in the number of milliliters of tenth normal sodium hydroxide required to neutralize 100 ml. of gastric content. The total acid represents the free acid, HCl combined with protein, plus acid salts and organic acids. There is a wide variation in the amount of free and total acid found in the stomach of a normal individual. In a normal adult this may vary from 0 to 30 units of free acid and from 5 to 40 units of total acid. Total anacidity is uncommon in young adults but increases with age so that about 30 per cent of males and about 20 per cent of females in the sixth decade have an anacidity. Normal acidity curves following a test meal, as well as those in patients with hypoacidity and hyperacidity, are shown in Figure 4. In general, patients with duodenal ulcer have increased volume and acidity. The presence of achlorhydria with gastric ulcer suggests that the lesion must be regarded as malignant until proven otherwise. Achlorhydria usually accompanies a diagnosis of pernicious anemia and occurs also with idiopathic hypochromic anemia.

It is frequently possible to identify *Mycobacterium tuberculosis* by recovering swallowed sputum from the gastric content when it is not possible to obtain sputum otherwise. A fasting specimen is obtained and the concentrate may be smeared and studied microscopically for acid-fast bacilli or injected in the guinea pig as a biological test for tuberculosis.

Gastric carcinoma may be diagnosed by cytologic technics utilizing recovered samples of gastric content. A normal washing may be

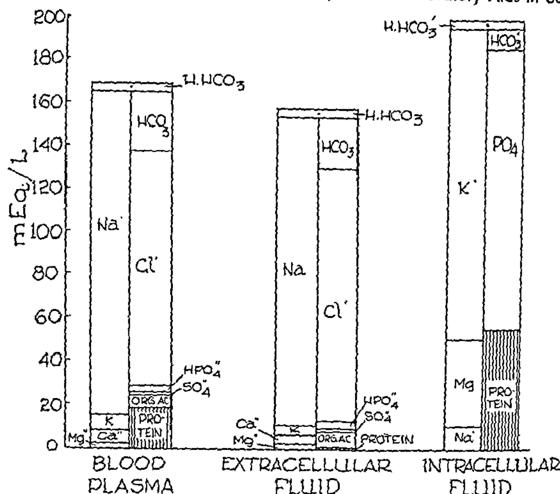

Fig. 3. The chemical composition of intracellular fluid, extracellular fluid, and blood plasma of man. (Adapted from Gamble.)

derangements as fistulas, hemorrhage, or draining wounds require careful evaluation and exact knowledge of the chemical composition of the extracellular fluid. Observations should be made on the patient of body weight, fluid intake and output, the specific gravity of the urine, and the blood count—including the hematocrit.

The volumes of the various compartments of body fluid can also be determined by special examinations. Methods are available to measure the red cell volume, plasma volume, the extracellular fluid, and the total body water. The serum electrolytes usually obtained are sodium, potassium, chloride, calcium, and magnesium; normal values are listed in Table 4. The chemical compositions of the intracellular fluid, the extracellular fluid, and the blood plasma are depicted in Figure 3.

TABLE 4. Normal Values of Serum Electrolytes.

	mEq/L	mg. %
Sodium	135.0–147.0	310.0–340.0
Potassium	3.5–5.5	18.0–22.0
Calcium	4.5–5.5	9.0–11.0
Magnesium	1.5–3.0	1.8–3.6
Carbon Dioxide (combining power)	25.0–30.0	56.0–65.0
Chlorides	100.0–110.0	350.0–390.0

GASTROINTESTINAL

Stomach. Gastric analysis is a commonly available test for the study of gastric physiology. An early morning fasting specimen is obtained through a nasogastric tube by the routine technic. If no free acid is present, as determined by the addition of Topfer's reagent, the patient is given a gastric stimulant such as caffeine sodium benzoate or histamine. Subsequent specimens are removed

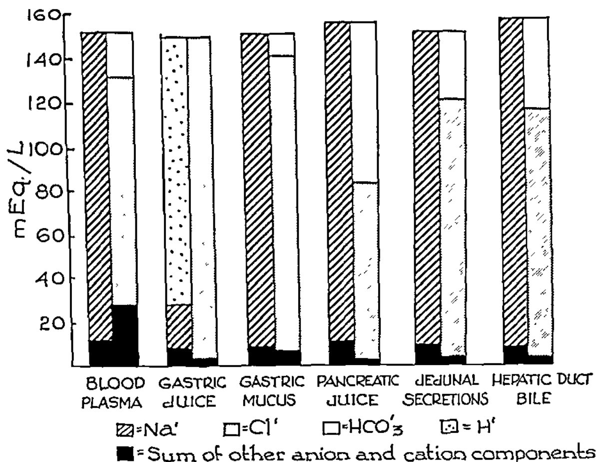

Fig. 5. Composition of intestinal fluids. (Adapted from Gamble.)

greatest value as a screening test for achlorhydria. When used for quantitative determination of the HCl in the stomach this method has not proven reliable. It is useful in determining the presence of acid in patients with active gastric bleeding in whom intubation is contraindicated or in those patients with severe angina or coronary infarction.

Duodenum. It is sometimes helpful to obtain duodenal drainage through an appropriate nasogastric tube, the position of which needs to be checked by fluoroscopy, although the presence of fluid with an alkaline pH strongly suggests that the tube has entered the duodenum. Injection of a 33 per cent magnesium sulfate solution through the tube will cause relaxation of the sphincter of Oddi and it may be possible to obtain gall bladder bile which is generally dark. This gradually becomes lighter and represents yellow or hepatic bile. Certain observations may be significant in examination of this aspirant, such as the presence of sand from the biliary tree, pus cells, bacteria (particularly typhoid bacilli), *Giardia lamblia*, or *Endamoeba histolytica.*

Chemical determinations may be made on intestinal fluids particularly at different levels of the bowel to determine the electrolyte composition of gastrointestinal secretions (Fig. 5). It is important to be aware of the composition of the intestinal fluids as loss through external fistulas or by vomiting or diarrhea must be replaced with a similar electrolyte solution to avoid serious depletions.

In addition to the direct examination of the duodenal drainage, useful information may be obtained by performing a secretin test consisting of the injection of one unit of secretin per kg. body weight intravenously, after a control specimen of duodenal contents has been obtained. The secretin causes a flow of pancreatic juice which is collected at 20-minute periods for the next 80 minutes. Gen-

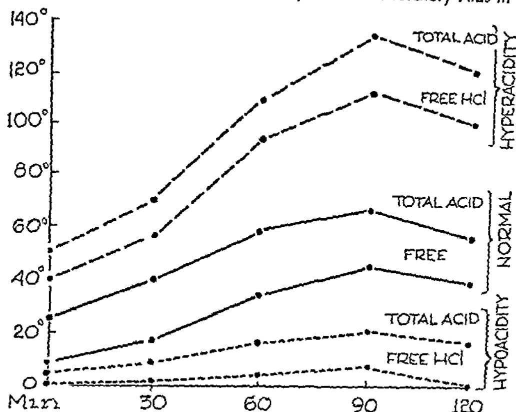

Fig. 4. The gastric acidity curve after test meal in patients with normal acidity, hyperacidity, and hypoacidity.

recovered, concentrated, smeared, and examined by the Papanicolaou technic.

Refined technics have been utilized whereby a solution of papain or trypsin is introduced into the stomach to dissolve the mucus covering the gastric mucosa and the malignant lesion, thus making a recovery of tumor cells less difficult. Another technic is the "brush" biopsy method, which consists of a small brushlike implement attached to a gastric tube that is passed into the stomach and entangles malignant cells in its fibers. When the tube has been removed the cancer cells can be recovered, smeared, and identified by cytologic technics. Another similar method utilizes an abrasive balloon attached to a gastric tube as described by Ayers.

In addition to the standard gastric analysis described above, there is a method of determining gastric achlorhydria described by Segal and Morton in 1950 using ion exchange resins (quinine carbacrylic resin). These authors demonstrated that the hydrogen ions of gastric juice below pH 3 displaced the quinine cation and this cation was excreted in the urine. The compound was administered orally in a fasting patient and urine was analyzed for the presence of quinine in a two-hour specimen. This test has been refined and various cation indicators substituted. Probably the most reliable indicator has been a carboxylic cation exchange resin containing Azure A dye as the indicator ion, administered by mouth to the fasting patient. The urine specimen is obtained after two hours, and the amount of dye in the urine is measured with a spectrophotometer at an optimum pH. With this technic, 0.6 mg. of dye must be excreted if free acid is present in the gastric juice. Most investigators have recommended the use of histamine or caffeine sodium benzoate to stimulate gastric secretion in conjunction with the resin. There is a 7 to 10 per cent error in patients who are known acid secretors and give false negative results with the test. In individuals with pyloric obstruction, malabsorption from the intestine, severe disease of liver or kidney, or with urinary retention, the test is not indicated. Most individuals report that in pernicious anemia or gastric carcinoma the absence of free acid in the stomach is confirmed. Perhaps this technic has the

creased to 60 or 80 per cent and is largely neutral fat. In obstructive jaundice, sprue, or conditions where absorption is disturbed, there is an excess of total fat in the feces, but this usually consists of fatty acids since the pancreatic lipase is not reduced in these conditions.

Liver. The multitude of metabolic activities occurring in the liver has resulted in development of numerous tests to evaluate the function of this organ in health and in disease. These tests may be utilized as follows: 1. elucidate liver physiology; 2. offer prognosis in established disease; 3. evaluate the results of therapy; 4. aid in the selection of operative or nonoperative therapy in a jaundice patient; and 5. detect subclinical liver disease. The liver has a tremendous reserve so that only 15 to 20 per cent of the liver parenchyma is necessary to sustain life. This large safety factor works to the disadvantage of the physician as significant areas of the liver must be involved before impairment of function is manifested by the various liver studies. In addition, most functions of the liver occur in histologically similar polygonal cells and these cells may perform some functions well and yet be defective in the performance of others so that a battery of tests is necessary for evaluation of liver function. A description of the more useful tests will follow; see Table 5 for normal values.

TABLE 5. Normal Values of Liver Function Tests.

Test	Normal value
Icteric index	4–7 units
Bilirubin, direct (immediate)	0.1–0.2 mg.%
Bilirubin, indirect (total)	0.2–1.0 mg.%
Serum proteins	
Albumin	3.5–5.5 gms.%
Globulin	1.5–3.4 gms.%
Fibrinogen	200–600 mgs.%
A/G ratio	1.6–2.0
Cholesterol, total	110–300 mgs.%
Prothrombin time	70–110% of control
Phosphatase, alkaline	3–5 units (Bodansky)
Cephalin flocculation	0–1+
Thymol turbidity	0–5 units
Zinc sulfate turbidity	5–14 units
Transaminase	10–40 units
Bromsulphalein (5 mg./kg.)	5% of dye or less in serum at 45 minutes.

The simplest estimation of the bilirubin content in the plasma is by the icteric index, which is obtained by matching the color of plasma or serum with dilutions of a standard solution of potassium dichromate. Normal values are between 4 and 7 units. The first detectable clinical jaundice occurs at 15 units. This is not a specific test as hemolysis of red cells, various drugs such as atabrine or dinitrophenol, or carotenemia may give a yellow color to the serum. The main value of the test is as a screening procedure and to follow the level of jaundice in patients under observation and treatment.

Hemoglobin is broken down in the reticuloendothelial system forming free bilirubin. This is indirect bilirubin which is fully soluble in water at the physiologic pH and is not excreted by the kidney. Indirect bilirubin, normally present in serum in concentrations of less than 1 mg. per cent, is conjugated in the parenchymal cells of the liver with glucuronic acid and forms bilirubin glucuronide. This is a water-soluble complex which gives a direct reaction with Ehrlich's diazo reagent. The maximum normal concentration in serum is 0.2 mg. per cent. Excesses beyond the normal maximum appear in the urine. The bilirubin glucuronide is excreted into the bowel via the common bile duct where, by the action of the intestinal flora, it is converted into a group of colorless chromogens which are called urobilinogen. The urobilinogen will react with Ehrlich's aldehyde reagent and is the basis for identifying urobilinogen in the stool. The urobilinogen produced in the intestine is then oxidized to urobilin which produces the orange-brown, normal color of feces. The oxidized form must be demonstrated by the Schlesinger test.

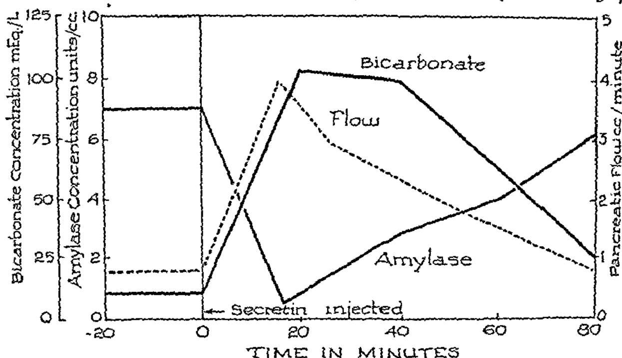

Fig. 6. Normal response in the secretin test. (Adapted from Dreiling.)

erally the drainage is examined for volume, bicarbonate concentration, amylase concentration, guaiac reaction, icterus index, and cellular elements. The first three observations characterize the pancreatic response to the secretin. In normal individuals there is a rapid increase in the rate of pancreatic secretion which quickly reaches a maximum and subsides at the end of 80 minutes. Normal individuals will secrete from 100 to 300 ml. during this period. Obstruction of the pancreatic ducts will cause a reduction of the flow. The bicarbonate concentration follows the volume but responds more slowly and lasts somewhat longer. The amylase concentration usually varies inversely with the pancreatic flow. The normal quantity of amylase produced over a period of 80 minutes equals six or more units per kilogram. Thus, patients with pancreatic tumors usually show a reduction in volume, while patients with extensive lesions that have destroyed significant portions of the secreting parenchyma may show some diminution of potency of the secretion. In acute pancreatitis this test is of little value; however, in chronic pancreatitis the volume tends to remain normal, but there is a marked lowering of the maximum bicarbonate concentration. Enzyme secretion is usually less affected. Figure 6 indicates the normal response to the injection of secretin.

Colon. The stool examination is the routine laboratory test conducted on feces. The presence of blood in the stool is of clinical significance and it is important to note whether this is bright blood presumably coming from the anus or rectum or dark blood coming from higher in the colon or terminal small bowel. If the stool is actually tarry in color this indicates the presence of blood from the upper gastrointestinal tract. In addition to the gross and microscopic examination of the stool, cultures may be obtained to identify various members of the typhoid-dysentery group. These cultures should be made on special media. The stool may be examined for urobilin, or urobilinogen which is referred to under the section on the liver. Occult blood is determined by the guaiac test and is usually a sign of an ulcerated lesion in the colon or small bowel.

It may be important to determine the quantity of fat in the stool and the proportion comprised of neutral fat and fatty acids. Normally, total fat in the stool is from 15 to 25 per cent by weight, neutral fat from 1 to 2 per cent, and fatty acids 9 to 13 per cent. In pancreatic insufficiency the total fat may be in-

mal values will be obtained. The test is normal early in infectious hepatitis but rises quickly to levels of 15 to 25 units.

The transaminase test is a measurement of the glutamic-oxalacetic transaminase which is an enzyme widely distributed in tissues, occurring in greatest concentration in heart muscle, skeletal muscle, brain, liver, and kidney, in decreasing order. Cellular destruction, such as that caused by acute myocardial infarction, liver-cell destruction, or damage to skeletal muscle, all produce marked elevation in the transaminase blood level. The following observations of transaminase levels in liver disease have been reported by Wroblewski and LaDue.

Carbon tetrachloride liver damage has produced elevations to 27,840 units.

Patients with infectious hepatitis or homologous serum jaundice have elevations of the transaminase level.

The serum transaminase is a relatively sensitive index of liver metastases except when there is involvement of the liver with lymphoma or leukemia.

Elevations occur in cirrhosis but are not constant and apparently reflect superimposed hepatitis.

Extrahepatic obstructive jaundice is accompanied by minimal elevation of the serum transaminase which responds to surgical correction of the obstruction.

Elevation of the alkaline phosphatase resulting from bone disease may be differentiated from that resulting from liver disease by the fact that the transaminase is not increased in the former.

The transaminase activity in the presence of liver disease does not necessarily correlate with the liver function tests in common use but does indicate liver cell destruction.

The liver synthesizes prothrombin from fat-soluble vitamin K, hence the determination of the prothrombin can be used as a test of liver function. The normal prothrombin time is from 70 to 100 per cent of the control. The test is not particularly sensitive in patients with lesser degrees of liver damage from hepatitis or intermittent obstruction. With obstructive disease, the lack of bile in the bowel will interfere with proper absorption of vitamin K. When the prothrombin time is lowered, 1 mg. of vitamin K can be given intravenously and the determination repeated in 24 hours. The patient with early obstructive jaundice or mild infectious hepatitis will have a rapid response to the vitamin K with a return to normal prothrombin time. If the prothrombin time does not respond promptly to vitamin K, this is an indication of severe liver damage.

The total serum protein, which normally runs from 6 to 8 gm. per cent, as well as the fractional proteins—specifically albumin, globulin, and fibrinogen—may be used as tests of liver function, as these proteins are synthesized in the liver from amino acids. The normal albumin level is 3.5 to 5.5 gm. per cent; globulin, 1.5 to 3.4 gm. per cent; and fibrinogen, 200 to 600 ml. per cent. Lowered levels or reversal of the albumin-globulin ratio, which normally is 1.2 to 2 usually, results from impaired liver function.

Serum cholesterol may be affected by liver disease; the normal cholesterol varies from 110 to 300 mg. per cent. Hypercholesterolemia usually accompanies early jaundice due to common duct obstruction.

Pancreas. The pathophysiology of the pancreas lends itself to study by various laboratory aids. Reference has been made heretofore to the secretions emptied into the duodenum and to the secretin test.

The serum levels of the various enzymes produced by the pancreas are utilized to indicate evidence of impaired function. The three major enzymes are amylase, lipase, and trypsin. Standard determinations of the first two are available. The normal serum amylase is determined by the digestion of a starch solution by the amylase in a specific amount of serum. The remaining starch reacts with iodine and the resulting color is read on a colorimeter. Normal levels are expressed in Somogyi units and range from 80 to 150.

The serum lipase test utilizes the liberation of tributeric acid from aqueous tributyrin by serum lipase. The liberated acid is titrated with standard sodium hydroxide. Normal levels range from 0.5 to 1.5 units (N/20 NaOH).

Only recently, a test to determine serum trypsin, has been described by Nardi and Lees. A polypeptide substrate with an amide linkage, vulnerable only to trypsin, has been synthesized. The digestion of the substrate is

Small amounts of the urobilinogen are reabsorbed from the intestine into the portal circulation, some is excreted by the liver and some by the urine. This may be identified by the use of Ehrlich's aldehyde reagent. The excretion of urobilinogen is one of the more sensitive functions of the liver and is reduced early in the course of parenchymal disease. This condition will cause an increase in the amount of urobilinogen in the urine. Hemolytic jaundice brings about an increase in the amount of bilirubin excreted in the intestine and results in an increase in urobilinogen content in both urine and stool. With biliary tract obstruction, the feces become clay colored and urobilinogen does not appear in either urine or stool since the bilirubin cannot reach the intestine.

The bromsulphalein test is widely employed as a liver function test. The reticuloendothelial cells of the liver excrete bromsulphalein into the bile; a decreased rate of excretion is evidence of liver damage. This test should not be performed when the patient is jaundiced or if a phenolsulfonphtholein (PSP) test has been performed recently. Five milligrams per kilogram of the dye are injected intravenously in the fasting patient. Blood is drawn, usually at 30 and 45 minutes, and serum is obtained, alkalinized, and compared with normal color standards. In the normal individual, 5 per cent or less of the dye remains in the serum at 45 minutes.

There are a number of other tolerance tests, less frequently performed, that determine the ability of the liver to detoxify or secrete substances injected intravenously or taken by mouth. The test agent or conjugant remaining in the blood or excreted in urine after being acted upon by the liver is used to measure hepatic function. The following tests utilizing these principles are listed for reference: fructose tolerance; galactose tolerance; hippuric acid test; lactic acid test; and rose bengal test.

The cephalin-cholesterol flocculation test of Hanger is a sensitive indicator of parenchymal liver cell damage and is simple to perform, dependable, and readily available. An emulsion of cephalin, made from sheep brain, and cholesterol is prepared. The addition of serum will cause a flocculation which is expressed in terms of 0 to 4+. The mechanism apparently is related to changes in the serum globulin. The test is strongly positive in hepatitis and is usually negative in early obstructive jaundice. A positive test in obstructive jaundice will occur as the parenchymal cells undergo damage from prolonged obstruction.

The thymol turbidity test of Maclagan also gives a good indication of hepatic parenchymal damage. The patient's serum is added to serially diluted solutions of thymol barbital and the degree of turbidity is read on a spectrophotometer. The normal values range from 0 to 5 units. This mechanism is not definitely understood but apparently the turbidity is produced in the thymol buffer by the interaction of gamma globulin and a lipoprotein component of the serum. The test rapidly becomes positive in infectious hepatitis and is useful when following the course of the disease. Patients with obstructive jaundice usually show normal values. Increase in the total serum lipids may produce some degree of thymol turbidity. This fact must be remembered in obstructive jaundice as there may be some elevation in the lipid level.

The serum alkaline phosphatase is useful in the study of obstructive liver disease and the normal level in serum is from 3 to 5 Bodansky units in adults and somewhat higher levels in children. In cases of obstructive biliary tract disease, 90 per cent of the patients have elevated levels of more than 10 Bodansky units. In patients with infectious hepatitis or hemolytic jaundice, the reverse is true. The alkaline phosphatase may also be elevated in certain bone diseases, in parathyroid disfunction, and in cholangiolytic hepatitis. In patients with normal or nearly normal serum bilirubin, elevation of the alkaline phosphatase occurs with chronic infiltrating diseases of the liver due to sarcoid, tuberculosis, Hodgkin's disease, and similar conditions.

The zinc sulfate turbidity test described by Kunkel is a simple method for the quantitative estimation of serum gamma globulin and is useful in differentiating between obstructive and nonobstructive jaundice. Normal values range from 5 to 14 units. Elevated levels may be found in many diseases in which there is an increase in serum gamma globulin. In patients with uncomplicated obstructive jaundice nor-

phthalein excreted is a relative index of the functioning tubular tissue. On the other hand, such factors as diminished blood flow to the kidney, delayed absorption when the drug is given intramuscularly, and certain types of liver disease may significantly alter the amount of phenolsulfonphthalein excreted in the presence of normal renal function. Nevertheless, if the test is properly performed and evaluated it may be extremely useful. The dye is injected intravenously, and the urine is then collected for two hours. Normally, at least 70 per cent of the dye injected is excreted within this period. The best results are obtained if the patient is hydrated before the test in order to increase the urinary output.

CLEARANCE STUDIES. A more exact definition of the discrete functions of the kidney requires the use of clearance technics (Table 6). With the exception of urea clearance, these technics have been employed primarily as research methods. Recent experience, however, indicates that discrete renal function tests may have prognostic significance, particularly following surgical procedures which interfere temporarily with renal blood flow (Table 7). For this reason these tests are described here briefly.

TABLE 7. Data Relating to Discrete Renal Function Studies in a Patient with a Thoracoabdominal Aortic Aneurysm.
(Resection required temporary interruption of the renal arteries. Recovery of renal function was evident by the third week after operation.)

DETERMINATION	BEFORE OPERATION	DAYS AFTER OPERATION 2	7	22
Glomerular Filtration Rate ml./min.	67	19	44	59
Renal Plasma Flow ml./min.	277	121	226	358
Renal Blood Flow ml./min.	461	212	396	596

The determination of urea clearance is perhaps the most useful test of renal function. Urea is a freely diffusible substance, but a small part of the urea is reabsorbed by the tubules and does not appear in the urine. For best results, the urea clearance should be performed when urine flow is above 2 ml. per minute so that the clearance is "maximal." When the urine output is less than 2 ml. per minute the clearance of urea diminishes in proportion to the square root of the urine flow. Using this relationship the "standard" clearance may be determined. Although the normal variation is large, the average maximal clearance for a normal adult is about 75 ml. per minute and the standard clearance is 54 ml. per minute. A reduction below 75 per cent of normal must occur, however, before the clearance can be considered definitely abnormal.

Specialized clearance studies are less useful clinically because they are more difficult to perform yet they are more accurate and specific than the renal function tests described above. For performance of these clearance studies, three variables must be measured as follows: 1. concentration of a solute in the urine, U; 2. quantity of of urine excreted during a unit of time, V; and 3. the simultaneous concentration of this substance in the plasma, P. Clearance of the solute is derived from the ratio UV/P and represents the smallest quantity of plasma from which the solute excreted in the urine could be obtained during unit time. This formula is similar to one used in determining urea clearance, but the difference lies in the fact that urea is partially reabsorbed in the tubules, whereas the substances employed in other clearance studies are completely filtered in the glomerulus; thus the *glomerular filtration rate* may be measured with such a solute as inulin, mannitol, or thiosulfate which is completely filtered in the glomerulus and is unchanged in the tubules. The ability of the glomeruli to remove a solute from the plasma in unit time can be determined accurately with this test.

Tubular reabsorption and secretion can be estimated by simultaneously measuring the rate of excretion of a urinary constituent and the glomerular filtration rate of inulin. Paraaminohippurate and Diodrast are actively secreted by the tubules when infused at a slow rate. Portions of these substances are bound to protein and only partially filtered. The remainder is secreted at a rate approaching

measured, thus enabling a quantitative estimation of the trypsin in the patient's serum. Normal individuals have little or no circulating trypsin present.

It is also possible to obtain indirect measurement of the circulatory enzymes by determining the antienzyme levels. A system containing an appropriate substrate and the specific enzyme is set up. The rate of digestion of the substrate can be determined and compared with a test system to which the patient's serum has been added. The per cent digestion as compared to the normal may be determined.

These tests are very sensitive to many pathological situations and are not used commonly owing to the lack of specificity.

Blood sugar levels are controlled by insulin secreted in the pancreas by the islands of Langerhans. The normal fasting level ranges from 80 to 120 mg. per cent. Diabetes mellitus is the disease of major importance that causes elevation of the blood sugar. With elevation of the glucose level, sugar appears in the urine where it can be detected by the Benedict test. The presence of ketone bodies such as acetone, diacetic and beta-hydroxybutyric acid may also be detected by appropriate urinalysis. There are many causes for elevation of the blood sugar and the appearance of sugar in the urine. A glucose tolerance test will help to clarify the cause of an elevated fasting blood sugar. Standard references are readily available for interpretation of abnormalities of glucose metabolism.

RENAL EXCRETORY SYSTEM

Routine analysis of the urine for the presence of protein, sugar, acetone, and formed elements should be performed in every case. In addition, determination of the amount and type of urine formed is also important. Measurement of the total daily urinary output together with extrarenal fluid losses, and comparison of these with fluid intake is the most practical measure of renal function in the surgical patient and provides a therapeutic guide as well. When more precise evaluation of kidney function is desirable, determination of urine and plasma solutes is indicated. This includes measurement of urea, creatinine, sodium, chloride, potassium, and the carbon dioxide combining power of the blood, and simultaneous determinations of sodium, chloride, and potassium in the urine.

In many instances it is essential to determine the ability of the kidneys to respond to water deprivation and to water excess. These tests measure the concentrating function of the kidneys and are usually performed by placing the patient on solid food, without fluid, for a twelve-hour period, followed by a similar period of high water intake. Normally the stimulus of restricted water results in an increase in specific gravity of the urine to a level of 1.025 to 1.030, the intake of excess water results in a fall to 1.003. The elaboration of urine of a fixed specific gravity is commonly seen in certain renal diseases. Under these circumstances the specific gravity of the urine is usually about 1.010 to 1.012; in other words, that of the glomerular filtrate.

The phenolsulfonphthalein excretion test is one of the most commonly used for estimation of renal function (Table 6). This substance is a dye which is excreted by the renal tubules. After injection, most of the dye combines with serum albumin, thus cannot pass the glomerular membrane, and is excreted by the tubules. The amount of phenolsulfon-

TABLE 6. Normal Values for Tests of Renal Function

Concentration and dilution: specific gravity of urine;
- After dry day 1.025 or more
- After water day 1.003 or less

Phenolsulfonphthalein:
- Intramuscular injection: 55–75% in urine in 2 hours
- Intravenous injection: 25% or more in urine in 15 minutes

Urea Clearance:
- 40 ml. or more blood cleared per minute. Variations of 75–125% of average normal

Renal Clearance (corrected to 1.73 square meters body surface area):
- Inulin clearance (C_I) (measure of glomerular filtration rate)
  - Males 124.1 ± 25.8 ml./min.
  - Females 119.0 ± 12.8 ml./min.
- Para-aminohippuric acid (C_{PAH}) (measure of effective renal plasma flow)
  - Males 654.0 ± 163.0 ml./min.
  - Females 594.0 ± 102.0 ml./min.
- Tubular maximum for PAH
  - Males 77.2 mg./min.
  - Females 77.2 mg./min.

mal values are 4 to 8 μg. per cent which are constant for men, women, and children. Occasionally, observations of 3 to 9 μg. per cent are seen in normal patients. Sources of error may be found in the use of syringes or collection bottles contaminated with iodine, or when preparation of the patient's skin for needle puncture is performed with tincture of iodine. In addition, the patient must not have had any iodine therapy (as Lugol's solution, cough medicine, or throat lozenges containing iodine) for three to four weeks prior to the test. The patient must not have had cholecystography, pyelography, or other diagnostic x-ray procedures employing organic iodine compounds such as priodax and lipiodol. These iodine compounds will cause interference and abnormally high determinations from three to six months after their use. Interference has been caused by intrathecal Lipiodol for as long as three years, and by organic iodine treatments for parasitic infections. Diuretic mercurial compounds produce erroneously low levels for short intervals by interfering with the chemical determination of iodine.

Normal serum cholesterol varies from 110 to 300 mg. per cent. Cholesterol is classified as a body lipid along with neutral fat, fatty acids, and phosphatids, of which it normally constitutes 20 to 40 per cent. Chemically it is an alcohol rather than a fat and is present in serum as free cholesterol, 30 to 60 per cent, and as cholesterol esters of fatty acids. Levels are usually increased in conditions in which blood fat is increased and may be an indication of the amount of fat present. There is not a close parallel between these two findings and actually there may be a divergence. The blood cholesterol is little affected by the fat content of the diet but is increased by foods rich in cholesterol. With hyperthyroid disease the blood cholesterol is lowered; with myxedema, cretinism, and hypothyroidism the cholesterol is elevated. Blood cholesterol is most important as a confirmatory test in hypothyroid conditions and changes in level are important in following the effects of therapy.

Radioactive iodine (I^{131}) is a highly satisfactory isotope for clinical use. Given in amounts that are completely undetectable chemically, radioactive iodine may be traced by the energy released in nuclear disintegration. It has a half-life of eight days and the beta particles and gamma ray emissions permit ready detection with the apparatus currently available. To investigate thyroid disorders tracer doses are given as sodium iodide generally containing 5 to 50 μc. I^{131}. The dose, given in 6 ounces of water to a fasting patient, is followed by a normal meal. Determinations should be obtained routinely at 24 hours after the ingestion of the isotope. More frequent observation may be helpful to detect early excretion of I^{131}. Isotopographic drawings of detailed neck scanning, preferably to scale, on the tracings of the patient, are very useful.

A number of factors must be considered in evaluation of the radioiodine test. In the hyperactive gland, iodine will be picked up in greater amount and secreted in protein-bound form in higher concentration than in the normal gland. Thus, if only one observation is made, the usual time being 24 hours, the peak uptake may have been passed and the determination may fall within normal levels.

A second radioiodine test measures the conversion of inorganic iodine to the organic form in the thyroid and the secretion of protein-bound radioiodine into the blood (PBI^{131}). The PBI^{131} in the hyperthyroid patient will be elevated at 24 hours and continue to rise to higher levels at 48 and 72 hours. If the iodine uptake alone is used at 24 hours, 7 per cent of hyperthyroid patients will have values within the normal range. Using both determinations at 24 hours, this error can be significantly reduced.

In acute and subacute thyroiditis the radioiodine uptake and the PBI^{131} determinations are usually low in the acute phase and remain low as the inflammatory process persists. Sedimentation rate is usually elevated during the acute phase. In Hashimoto's thyroiditis the serum protein-bound iodine varies. The I^{131} uptake studies range from 6 to 83 per cent, and the PBI^{131} is always elevated to hyperthyroid levels. Thyroid stimulating hormone (TSH) administration will fail to produce a rise in the I^{131} uptake which, along with splenomegaly and abnormal liver function tests, may suggest Hashimoto's disease

complete removal from the plasma during a single circulation through the kidney. Thus, clearance of these substances reflects renal plasma flow and total renal blood flow may be calculated from the hematocrit value.

Maximal tubular excretory capacity is measured by increasing the plasma concentration of para-aminohippurate or Diodrast to a point where the maximal excretion rate of these substances is reached.

Maximal tubular reabsorptive capacity reflects the point at which substances normally absent in the urine appear as a result of increasing plasma concentration. Glucose is frequently used for this test since it is completely filtered but reabsorbed in the tubules up to a relatively constant maximal quantity. Beyond this maximal quantity, glucose appears in the urine and, thus, the capacity of the tubules to absorb substances may be accurately determined with this substance.

ENDOCRINE

Thyroid. A careful history and physical examination of the patient are of equal importance to the five commonly performed laboratory aids used in the diagnosis of thyroid disease (Table 8). The basal metabolism test (BMR), which is frequently performed and readily available, is a determination of the total energy produced by the combustion of food substances in the body under basal conditions; i.e., when the individual is fasting and is physically and mentally at rest and at ease. *The digestion of food will raise the* BMR by 10 to 15 per cent and any physical or mental activity will raise the determination proportionally. Several simple closed circuit machines are available for general use. Essentially, *the patient, in a fasting and basal state,* breathes into an air chamber containing an excess of O_2. The CO_2 is removed with a soda-lime filter. The volume of air in the apparatus is recorded on special graph paper, by which the oxygen consumed can be measured directly. Corrections are made for temperature, barometric pressure, and moisture, and the value obtained is then converted into energy equivalents (calories per hour) by standard tables. *The basal metabolism is usually* expressed in kilocalories produced per square meter of body surface per hour. Aub and DuBois' tables, based on surface area, are most extensively used. The standards of Benedict and Talbot *may* be used *for children.* Thus, the calories per square meter of body surface per hour are compared with the standard tables and a plus or minus per cent determination is obtained.

TABLE 8. Laboratory Findings in Normal, Hypothyroid, and Hyperthyroid Conditions.

Determination	Normal	Hypothyroid	Hyperthyroid
BMR	−10% to +15%	below −10%	above +15%
PBI	4–8 μg.%	below 4 μg.	above 8 μg.
I_{131}	20–50% uptake	below 20%	above 50% uptake
PBI_{131} (24 hrs.)	.010–.086%	.003–.054%	.085–1.45%
Cholesterol	110–300 mg.%	above 300 mg.%	below 110 mg.%

The basal metabolism, as expressed in kilocalories *per hour, is greater in early childhood* and decreases with age. It is 7 to 10 per cent lower in women as compared with men. The actual test is fraught with many chances for error. Some common errors are: leakage of *air around the nose clip, the mouthpiece, or* through a perforated ear drum; obstruction of valves; incomplete absorption of CO_2; and apprehension, restlessness, or discomfort on the part of the patient. Usually the test is performed *on three occasions to check the consistency* of the determinations.

Another disadvantage of the BMR is that changes of considerable magnitude may occur but still be without significance to the observer. *Although a patient with a BMR of* −10 per cent may have an elevation of 30 per cent to +20 per cent, this determination is not particularly significant without knowledge of a previous level. Therefore, objective *tests of thyroid function are more helpful.*

The protein-bound iodine (PBI) test is a definite aid to diagnosis in thyroid disease. The determination gives a direct estimate of the amount of circulating thyroid hormone, which is made up mainly of thyroxin, and is particularly useful in diagnosis of mild hyperthyroidism or hypothyroidism. *Present technics* permit the test to be performed with *accuracy in well-controlled laboratories.* Nor-

level this ion is mobilized from the bone resulting in demineralization. The excessive mobilization of calcium phosphate results in an elevation of the serum calcium level. Inorganic phosphorus in the serum of adults ranges from 3 to 5 mg. per cent and in children from 4 to 7 mg. per cent. Phosphorus in organic combination in the blood, particularly in the erythrocytes, is far greater than the inorganic phosphorus, but no information of practical clinical value has been obtained from its estimation. In hypersecretion of the parathyroid glands the phosphorus is usually low, the serum calcium becomes elevated, decalcification of bones takes place, and the patient exhibits signs of muscular weakness and hypotonia. Bone cysts and spontaneous fractures occur; the typical picture of osteitis fibrosa cystica. Large doses of parathormone or vitamin D may cause an increase in the phosphorus level due to the increased solubility of calcium phosphate. A high calcium, low phosphorus ratio may occur in myelomatosis and malignant metastases to bone. In hypoparathyroidism from parathyroidectomy, the phosphorus level rises as the calcium falls. With healing fractures the phosphorus level may be elevated. Advanced nephritis with acidosis will also cause elevation.

The normal alkaline phosphatase level is from 1.5 to 4 Bodansky units and is considered to be a good estimation of the osteogenic activity of recalcifying or newly calcifying bone. Hence, in the critical postoperative period following operation for hyperparathyroidism manifested by osteitis fibrosa cystica, it is extremely useful in predicting the amount of recalcification and the need for calcium. In the first few days after operation the determination may range from 2 to 20 Bodansky units, and will gradually return to normal over a period of several weeks.

Calcium excretion in the urine ranges from 0.1 to 0.3 gm. per 24 hours. Hyperfunction of the parathyroid glands, or injection of parathormone, causes an increase in excretion that results in a negative calcium balance.

The hyperexcretion of calcium in the kidneys results in supersaturation in the urine and deposition of calcium phosphate or oxalate crystals in the urinary tract. This may result in stone formation or in deposition in the renal parenchyma, and may lead to impaired renal function through either obstruction or damage to the renal cortex.

The normal phosphorus excretion in the urine is from 0.9 to 0.11 gm. per 24 hours, which is increased by hyperparathyroidism or the injection of parathormone. In patients with hypoparathyroidism, who are excreting large amounts of phosphorus, injections of parathormone fail to increase the output. This finding has been suggested as a test for hypoparathyroidism by Howard, et al.

Adrenal. The adrenal gland secretes three main groups of steroids.

The first group, called the "sugar hormones," is concerned with the maintenance of a normal blood sugar level. These steroids also modify carbohydrate, fat, and protein metabolism, permitting an individual to sustain long periods of fasting. They consist of corticosterone and hydrocortisone and are measured as 17-hydroxycorticoids in either blood or urine. In normal individuals the excretion in urine consists of 5 to 6 mg. per 24 hours. The second group is known as the "androgenic" steroids and is represented by such substances as adrenosterone and dehydroepiandrosterone. These steroids produce nitrogen retention and aid anabolic or anticatabolic processes. The adrenal androgens are measured in the female by determining the excretion of 17-ketosteroids. However, of the urinary 17-ketosteroids in the male, only two-thirds are derived from the adrenal while one-third is of testicular origin. Normal excretion in urine in males is 8 to 21 mg. per 24 hours and in females about half this amount, 4 to 14 mg. per 24 hours. The third type of steroids is the "salt-retaining" group of which the principal compound is aldosterone. It is possible to measure the output of aldosterone in the urine by assay methods but it is not commonly done. Adrenal insufficiency or hyperactivity may be manifested in acute or chronic form and may reflect changes in any or all of the three characteristic types of steroids produced.

HEMATOPOIETIC SYSTEM

The status of the blood and blood-forming organs is of vital significance to the surgeon in the diagnosis and treatment of surgical

and prevent unnecessary surgical intervention.

Thyroid carcinoma, particularly the papillary and follicular types, will take up, or can be caused to take up, radioiodine. The administration of propylthiouracil or TSH may cause the tumor or metastases to take up I^{131}. The undifferentiated carcinomas will not pick up iodine.

Radioactive iodine has been used to differentiate between benign and malignant nodules in nodular thyroid diseases. Malignant thyroid tissue concentrates less radioiodine than normal tissue. The so-called "hot" nodule is one that takes up more I^{131} than do other parts of the gland; the "cold" nodule collects less than the involved side. The "warm" nodule collects about the same I^{131} as the uninvolved gland. Thus the "hot" nodules, even if solitary, are usually benign, while about 10 per cent of the "warm" nodules and about 30 per cent of the "cold" nodules are malignant.

Parathyroid. The normal serum calcium level is from 9 to 11 mg. per cent (Table 9) which is only slightly affected by the oral intake of calcium. The level is largely regulated by parathyroid hormone which is secreted by the parathyroid glands. Calcium excesses are excreted by the kidneys and deficits are made up by mobilization of calcium from the bones. Prolonged decrease in calcium intake together with increased losses will result in a diminished serum level (Table 10).

TABLE 9. Normal Levels of Laboratory Tests Useful in the Study of Parathyroid Disease.

Test	Normal Level
Serum Calcium	9.0–11.0 mg.% (4.5–5.5 mEq./l.)
Serum Phosphorus	3.0–4.5 mg.% (1.0–2.3 mEq./l.)
Serum Alkaline Phosphatase	1.5–4.0 Bodansky units
Urine Calcium	0.1–0.3 gm./24 hrs.
Urine Phosphorus	0.09–0.11 gm./24 hrs.

TABLE 10. Types of Tetany (from Best & Taylor Physiological Basis of Medical Practice).

	Calcium	Bicarbonate	Chloride	pH	Phosphorus
Infantile or idiopathic tetany	Reduced	Normal	Normal	Normal	Normal or reduced
Tetany of osteomalacia	Reduced	Normal		Normal	Normal or reduced
Tetanies of sprue and celiac rickets	Reduced	Normal			
Gastric tetany	Normal	Increased	Reduced	Increased	Increased
Bicarbonate tetany	Normal	Increased	Reduced	Increased	
Hyperpneic tetany	Normal	Increased		Increased	
Parathyroid tetany:					
(a) Experimental	Reduced	Normal		Normal	Increased
(b) Post-operative	Reduced	Normal			
Phosphate tetany (Na_2HPO_4)	Reduced	Normal	Normal or increased	Normal or increased	Increased
Citrate tetany	Reduced				
Tetany due to calcium and vitamin D deficiency	Reduced				
Tetany due to magnesium deficiency	Normal				
Guanidin tetany	Normal or slightly reduced				Increased

Serum calcium exists in nondiffusible and diffusible forms. The former is bound to the protein molecule chiefly in the albumin fraction and comprises 45 per cent of the total (4 to 5 mg. per cent). Most of the diffusible calcium is in the ionized form. Variations in the total serum protein will influence the serum calcium level and therefore the calcium level varies directly with the protein level.

Parathormone acts on the renal tubules to increase the excretion of phosphorus. In attempts to preserve the serum phosphorus

level this ion is mobilized from the bone resulting in demineralization. The excessive mobilization of calcium phosphate results in an elevation of the serum calcium level. Inorganic phosphorus in the serum of adults ranges from 3 to 5 mg. per cent and in children from 4 to 7 mg. per cent. Phosphorus in organic combination in the blood, particularly in the erythrocytes, is far greater than the inorganic phosphorus, but no information of practical clinical value has been obtained from its estimation. In hypersecretion of the parathyroid glands the phosphorus is usually low, the serum calcium becomes elevated, decalcification of bones takes place, and the patient exhibits signs of muscular weakness and hypotonia. Bone cysts and spontaneous fractures occur; the typical picture of osteitis fibrosa cystica. Large doses of parathormone or vitamin D may cause an increase in the phosphorus level due to the increased solubility of calcium phosphate. A high calcium, low phosphorus ratio may occur in myelomatosis and malignant metastases to bone. In hypoparathyroidism from parathyroidectomy, the phosphorus level rises as the calcium falls. With healing fractures the phosphorus level may be elevated. Advanced nephritis with acidosis will also cause elevation.

The normal alkaline phosphatase level is from 1.5 to 4 Bodansky units and is considered to be a good estimation of the osteogenic activity of recalcifying or newly calcifying bone. conditions. It has become routine practice to examine the cellular elements of the peripheral blood as a part of examination of the patient. In many laboratories the routine blood studies performed upon hospital admission consist of erythrocyte, leukocyte, and platelet counts, measurement of hemoglobin concentration, packed cell volume, and microscopic examination of a stained blood film. This type of study will reveal most of the common abnormalities; i.e., anemia, polycythemia, leukopenia, leukocytosis, thrombocytopenia and the presence of abnormal cellular forms.

For a study of coagulation, the following tests are useful: 1. bleeding time; 2. clotting time; 3. prothrombin time; 4. prothrombin consumption; 5. thromboplastin generation; 6. cross-matching with plasma or serum from patients with known deficiencies; and 7. circulating anticoagulant test. In anemias it may be necessary to identify the hemoglobin type. This is particularly important when sickle cell anemia or thalassemia is suspected. The normal hemoglobins A (adult) and F (fetal) may be differentiated from the abnormal hemoglobins D, E, G, H, I, and J by three processes, namely alkali denaturation, electrophoresis (Tiselius), and paper electrophoresis.

The survival time of the erythrocyte can be measured by the injection of radioactive iron or sodium chromate, or of erythrocytes labeled with C-51.

Hematopoiesis is readily studied by examination of the bone marrow.

Whenever routine blood studies disclose an abnormality the nature of which is not readily apparent, consultation with a hematologist should be obtained. A list of blood examinations routinely performed in the hematology department at Tulane University and the normal values are shown in Figure 7.

BACTERIAL INFLAMMATION

Historical Survey
Prophylaxis: Asepsis
Antisepsis
Surgical Bacteriology

Bacterial inflammation is also called infection and is due to the invasion of either normal or already damaged tissue by bacteria. Infection is evident clinically by the cardinal signs of inflammation, but in a much more violent degree, and by the frequent development of pus and of systemic manifestations such as fever, chills, and prostration. The details of spontaneous infections, wound infections and the role of chemotherapy will each be discussed in separate chapters. Here only the general features of bacterial inflammation will be described.

In the days before Lister discovered the nature of bacterial inflammation, surgical wounds practically always became infected. Surgical mortality therefore was high. The conquest of bacterial inflammation ranks in importance with the discovery of anesthesia, for together they were responsible for the tremendous advance in surgery during the past century.

HISTORICAL SURVEY

It is difficult for present day surgeons to realize the revolting conditions before the Listerian era. The offensive smell emanating from a hospital betrayed the presence of surgical patients. Nearly all operations were followed by suppuration, septicemia, or gangrene. The mortality was often appalling; if a patient had a simple laceration dressed in such a hospital, he would be almost sure to develop a serious infection. It is not surprising that Joseph Lister, as a young surgeon at Glasgow, on seeing these foul-smelling surgical wounds should have thought of the contemporary experiments of Louis Pasteur on fermentation and putrefaction. Indeed the surgical wounds of that day did putrefy It was undoubtedly the work of Pasteur which influenced Lister, even though it was Schwann in 1837 who first showed that putrefaction could be prevented by heat and was therefore due to living organisms. Lister, by analogy, argued that the putrefying wounds were also due to living organisms, but obviously he could not use heat on patients' tissues. To kill bacteria, therefore, he selected the antiseptic phenol, probably because it was then used to deodorize the putrefying sewers of the nearby city of Carlisle.

Lister, because he emphasized the use of chemicals to combat infection, is credited with being the discoverer of antiseptic surgery. Indeed, his paper in 1867 was entitled, "On the Antiseptic Principle in the Practice of Surgery." Although Lister's teachings now seem so obvious and fundamental, he spent a large part of his life defending his thesis and often found himself in bitter polemics with his English colleagues. In America, Lister's technic was also slow to become generally adopted. In Germany, however, his work was hailed with much enthusiasm and acclaim. His visit there in 1875 grew into a triumphal procession. It is to the Germans, moreover, that we owe our present ideas of aseptic surgery which is an extension of Listerism. Von Bergman, by introducing steam sterilization in 1886 and the elaborate aseptic ritual in 1891, is generally credited with originating the conception of aseptic surgery which really, however, is more of an outgrowth of the observations of Oliver Wendell Holmes and the Viennese obstetrician, Semmelweiss, than of the teachings of Pasteur and Lister. Pasteur

and Lister were concerned with living organisms and their eradication. Dr. Holmes knew nothing of bacteria, but did know that contact between one infected patient and another would result in a transfer of the infection, because something was carried from the first to the second patient and usually by the attending physician's hands; as early as 1842 he wrote advising doctors to cleanse their hands thoroughly before and after attending each parturient woman in order to reduce the incidence of puerperal fever. Semmelweiss, in Austria, made the same observation independently, although his first paper was not published until 1849. At that time childbed fever often played as much havoc in the lying-in hospitals as surgical infections did in the surgical wards. Like Lister in England, Semmelweiss entered into long controversies with his colleagues who generally refused to listen to his accurate and important teachings. Because of this he is said to have become utterly broken in spirit by the time he died. Recent historical studies by Kirkwood (1) have shown that Thomas Watson's observations antedated those of Semmelweiss and Holmes. In his *Lectures on the Principles and Practice of Physics* (1843) he described epidemics of puerperal fever in various parts of England as early as 1789 and stated unequivocally that "I believe them to be instances of direct inoculation."

The importance of contact contamination still forms one of the backbones of modern aseptic surgery. The principle was well expressed by Theodore Kocher, who was discussing many years ago the then widely debated question of the necessity of wearing rubber gloves during an operation. His surprising aphorism was to the effect that it was much more important to wear gloves *between* than during operations. This indeed would tend to prevent outside contamination. The use of rubber gloves in surgical operations was introduced by the American surgeon Halsted in 1890. Today the careful surgeon wears rubber gloves not only during an operation, but also whenever he touches infectious material, as, for example, when dressing or examining suppurating wounds. There must be no opportunity for any virulent organism to harbor itself on his hands. This should be true even outside of the hospital.

PROPHYLAXIS: ASEPSIS

The prevention of infection applies to wounds inflicted in the operating room as well as to those sustained accidentally outside. In general, the means used in the former are called asepsis, the latter antisepsis. Although there is considerable overlapping, each will be discussed separately. Chemotherapy as a means of prophylaxis is described in detail in the next chapter.

Asepsis. The principle of aseptic surgery is based largely upon the exclusion of all bacteria from the wound inflicted by the surgeon (Fig. 1). In this way healing takes place without infection; i.e., aseptically, or by first intention. The setup for maintaining such a technic is an elaborate one and requires attention to detail and painstaking daily and hourly scrutiny to see that no loopholes admit any offending organism. Such aseptic surgery is like a chain which is only as strong as the weakest link, and it is the problem of the surgeon and operating room personnel to see that no virulent bacteria get into the operative field, and through a break in technic create a weak link which destroys the entire scheme.

Such perfection in actual practice is almost impossible to attain, largely because of two sources of contamination.

The first source is the surgeon's hands and the patient's skin which, with the ordinary routine, cannot be rid of all of their bacterial inhabitants. Although the surface of the skin can be sterilized, the deeper epidermal layers as well as the recesses of hair follicles and sweat and sebaceous glands harbor organisms which are practically impossible to eradicate. The normal bacteriology of the skin has been well described by Lovell (2).

The second source of contamination is the bacteria in the dust of the air. Lister was much concerned with air contamination and used a carbolic spray, which may perhaps have killed the organisms in the air but proved to be too irritating and poisonous for general adoption. Air contamination may be greatly minimized by certain mechanical means mentioned below. However, it has been found that these two sources of contamination, i.e., skin and air, can be so greatly reduced that perfect healing will result. The

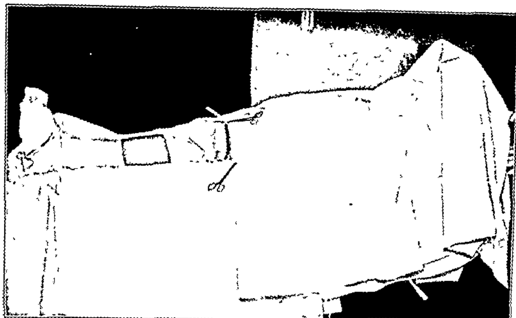

Fig. 1. Proper method of draping for an aseptic operation on the left lower leg.

following are the means by which this is achieved.

Methods of Surgical Sterilization. 1. *Mechanical means* comprise ordinary cleanliness by the use of soap, water, and scrubbing brush on the walls, floors, and ceiling of the operating room.

The area of the patient's skin about the proposed incision is also mechanically cleansed by careful shaving and washing. When shaving is carried out 12 hours or more before the proposed operation, scratches or tiny abrasions may be produced through which latent infection may occur. For this reason, many surgeons prefer to have the shaving carried out on the morning of operation.

The hands of all members of the surgical team are subjected to especially vigorous cleansing, particularly of the crevices under the nails and cuticles. Warm water is important for it promotes sweating, thereby bringing to the surface bacteria embedded in the depths of the sweat and sebaceous glands. The use of a good soap or the newer detergents improves the efficacy of mechanical cleansing, as discussed below. The stirring of dust from the floor is minimized by limiting the number of those walking about and by proper cleansing and treatment of floors to decrease dust. Clean, white shoes which have never been used outside are also advisable.

2. *Heat* is widely used in many ways to destroy bacteria, particularly in the sterilization of dressings, instruments, and other apparatus used during the operation. It is important to realize that destruction of bacteria particularly of spores, by heat, is due to coagulation of the bacterial protoplasm. This procedure requires the presence of moisture unless very high temperatures approaching that of an actual flame are used. For this reason, wet heat is much more efficient than dry heat; boiling water is much more effective than heated air. Most efficient of all is moist, *saturated steam vapor which is made to attain* a temperature much above that of boiling water by containing the steam in a closed chamber (autoclave) under sufficient pressure. The chief value of the increased pressure is its effect on raising the temperature. Thus, pure steam under a pressure of ten to fifteen pounds will attain a temperature of 115° to 120° C. (240° to 248° F.). Under such conditions the most resistant pathogenic spores will be destroyed in a very short time. Another great advantage of moist steam under pressure is its great penetrating power which enables one to sterilize large amounts of dressings, sheets, and such materials, if not too tightly packed. The condensation of the steam as it penetrates the cooler layers of fabric also aids greatly, for a thin film of moisture is thereby deposited and the local

temperature increased tremendously due to the liberation of heat during condensation.

3. *Chemicals* are of minor importance for sterilization, and even then only for surface sterilization. In the past, various chemicals were used for this purpose, as listed in Table 1, p. 67, now almost exclusively displaced by the synthetic detergents and other agents. The earliest of the former group were called cationic detergents, a popular example of which was Zephiran. Most of them were not only cleaning agents with bacteriostatic properties, but also left microscopic protective films over the skin. Unfortunately, bacteria continued to gather under the film from the deeper recesses and were released when the film was broken. A more recent and commonly used preparation is a combination of a good soap and hexachlorophene, which is a bacteriostatic agent and also forms a protective film over the skin. Some surgeons use a 3 per cent hexachlorophene in 90 per cent propyl alcohol, and 10 per cent dodecyl alcohol. The film produced is then removed by scrubbing the area later with a soap containing the same chemical. In an extensive study by Freeman and Young (3) a great diminution in the incidence of wound infection was found following the use of a synthetic detergent for skin preparation. Thus in 1,200 control cases in which the usual technic was employed, 7 per cent of the cases showed evidence of wound infection whereas, with the use of the synthetic detergent, only one serious infection and three stitch abscesses were noted in 1,100 consecutive cases. Phenol, the backbone of Lister's antiseptic technic, is rarely used now except to cauterize infected tissue and to sterilize sharp instruments which might be dulled by boiling. Gaseous formaldehyde is often used to sterilize cystoscopic and bronchoscopic instruments.

4. Gentle irrigation of the wound after closure of the fascia, using isotonic saline, tends to remove particles of fat, debris, and even bacteria released from the deep layers of the skin. A microscopic study of the location and distribution of these skin bacteria has been reported by Lovell (2). That bacteria actually are frequently present is shown by a study by Hunt (4), of 28 clean abdominal wounds just before skin closure. Culture of the wound secretion showed 40 to 1,680 bacterial colonies in all but three cases, even though 19 healed with no evidence of infection, and the remainder showed only a mild exudate between the skin edges, or around the sutures. The one case with 1,680 colonies developed a mild postoperative thrombophlebitis.

Wounds treated by gentle irrigation before closure are much more likely to heal drier and with less moisture around the sutures or between the skin edges.

Breaks in Aseptic Surgical Technic. The development of a postoperative wound infection in what should have been a perfectly healed incision means, of course, that bacteria have slipped in through some loophole in spite of the elaborate precautions; the chain has developed a weak link. It is important, therefore, to make careful observations of all such infections, even though trivial, and to culture the pus in order to identify the contaminating organism. Each step in the preparation of dressings, solutions, and instruments must be carefully investigated, sterilizers checked, autoclaves examined, and chemical solutions analyzed bacteriologically. Air-borne contamination from dust is also investigated and eliminated as far as possible, along lines already discussed. In most cases, however, the fault lies with the surgeon, operating team or personnel (Fig. 2).

These may be described as follows:

1. The *mouths and throats* of the operating room personnel emit countless bacteria into the air with each expiration. These cause no trouble ordinarily when efficient masks are worn. To be effective, masks must efficiently strain the exhaled air of all droplets. Masks containing an impermeable layer such as cellophane are unsatisfactory because they merely deflect the exhaled air. Much more practical and scientific is the use of such substances as cellucotton or flannel (de Takats 5) which have more of a tendency to filter the exhaled air. Masks must cover both mouth and nostrils, and of course must be comfortable to the wearer. They must be worn by all entering the operating room. When droplets are ejected while talking, or especially by coughing, sneezing, laughing, or clearing the throat, the danger of air contamination is greatly increased, even though masks are worn. Such actions are therefore

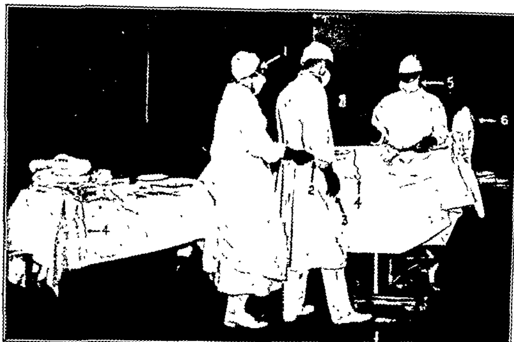

Fig. 2. Common errors and breaks in technic to be guarded against in the operating room: 1, nurse's hair incompletely covered by cap; 2, passing instruments should never be done behind another person; 3, the gloved hand should not fall to the side but must be kept above the level of the operating table; 4, sutures must not be allowed to drag below the field of operation; 5, the nose as well as the mouth must be covered by the mask; 6, draping over the anesthetic screen must be complete.

interdicted in the operating room, especially over an open wound. Regardless of masks, moreover, the presence of any person with a respiratory infection in an operating room courts serious danger, not only because such individuals are likely to cough uncontrollably, but, of more importance, the bacteria they exhale are so virulent that the deposition of relatively few on the wound may result in a serious infection. The importance of proper circulation of uncontaminated air through the operating rooms in the prevention of wound infection has recently been emphasized by Ross and associates (6).

2. The *skin of the surgeon's hands* as well as that of the other members of the team form a second source of contamination. The danger of contact infection has already been emphasized. The presence of infected lesions on the hands, even if slight, should exclude the individual from scrubbing up for the operation, because rubber gloves are not absolute in their protection. Not only are they porous, but they may become torn or punctured, sometimes without being noticed, and virulent organisms spilled into the wound (Fig. 3).

Contamination of the surgeon's hands outside the operating room may persist despite the usual preparation. As mentioned earlier, this was the reason Kocher suggested, perhaps facetiously, that the surgeon wear rubber gloves before rather than during operation. Nevertheless, it might be worthwhile to follow the suggestion of Poth that all surgeons use a soap containing hexachlorophene whenever they wash their hands as part of their routine toilet.

3. The *patient's skin* is a third link which may weaken the chain. Unless the operation is urgent, the presence of even minor infections in the field of the proposed incision contraindicates operation until the furuncle, dermatitis, or ulcer is healed. The presence of a large abscess anywhere, even though not in the field of operation, may also be a possible source of contamination. If the patient has a respiratory infection the same danger is present. Such infections may give rise to a bacteremia which will lead to a wound infection by the deposition of blood-borne organisms in the field traumatized by the surgeon. In such cases when the operation is one of election it is safer to wait until the offending lesion is healed.

4. A fourth loophole is *faulty sterilization*

A

B

C

D

E

F

Fig. 3. Various steps in the process of "scrubbing up," or aseptic preparation. A, scrub the hands and arms up to and above the elbows for ten minutes with a brush, soap, and running water; B, allow water to drain off the elbows; C, dry hands and arms with a sterile towel; D, bathe the hands and arms in alcohol or acetone solution; E and F, proper method of putting on gloves unassisted. Note that the outside of the glove is not touched by the skin. The use of synthetic detergents has shortened the period of "scrubbing up" and made it more efficient.

with autoclaves. As mentioned above, only moist heat under pressure effectively destroys spores. The presence of air in the autoclave, improper packing of supplies, etc., may seriously interfere with effective sterilization.

5. *Catgut* is a fifth possible source of contamination since it is prepared from an infected tissue, i.e., the lower small intestine of sheep. Constant and alert precautions on the part of the makers of catgut usually yield sterile sutures, but the danger is nevertheless present and numerous instances of infected catgut have been reported.

6. A final loophole in the aseptic scheme may occur by a *gross break in technic*, i.e., touching a sterile with a nonsterile object. Every surgeon and nurse must have an almost automatic alertness about such sources of contamination, a sort of second nature which makes it literally impossible for any nonsterile object to touch the field of operation or anything which comes in contact with it.

Other Factors in Prophylaxis. Although the methods just outlined, if rigidly carried out, will eliminate most bacteria from the operative field, a few may persist in the deep layers of the patient's skin or enter from those circulating in his blood. Most surgeons realize, however, that these few bacteria do not interfere with perfect healing because, with good surgical technic, the wound can easily cope with them without infection. Emphasis must be placed, therefore, on the fact that these bacteria become important only when their multiplication is aided and abetted by faults of operative technic, factors which are never overlooked by careful surgeons. Most of these factors of operative technic are described in detail in later chapters. They comprise such features as the *gentle handling of tissue*,—so aptly emphasized recently by Ross (7)—*careful hemostasis, and avoidance of tension* in placing sutures; emphasis on these and other similar details formed an important part of the teaching of W. S. Halsted and others before the beginning of this century. Halsted also made numerous technical contributions such as rubber gloves, silver foil, gutta percha drains, and others.

Halsted was also an early advocate of the use of silk rather than catgut for sutures because, among other reasons, he felt that fine silk insured more careful technic, itself an important factor in aseptic healing. The trend toward the greater use of silk has continued, especially in more recent years. The reports by Whipple, Meleney, Howes, and Harvey over two decades ago, on the role of the suture in wound healing and in infection, probably played an important part in this change. Suture material is discussed in more detail in Chap. 14.

ANTISEPSIS

In contrast to asepsis, antisepsis finds its modern application in the accident room where wounds are seen which were sustained outside the hospital and often under conditions of maximum contamination, so that the open tissue is covered with millions of bacteria. A clear distinction should here be made between a contaminated wound and an infected wound. The difference is one of time and of treatment. Most badly contaminated wounds will become infected in the course of time without treatment. Some mildly contaminated ones may heal per primam. Only time tells. However, if a badly contaminated wound is seen early enough and the contamination adequately eliminated before the bacteria have gained a foothold, infection can almost always be prevented (see Chap. 14). To accomplish perfect healing is, therefore, the aim even in such cases. Here, indeed, is practiced true antiseptic surgery after the manner of Lister. If antisepsis is achieved and the wound is rid of the contaminating organisms the necessary surgery can then be done and the wound closed with all the precautions of aseptic surgery and perfect healing will follow. Mechanical means such as cleansing and débridement, as described in detail later, are much more important than antiseptic chemicals.

In open contaminated wounds, moreover, antiseptics may do much damage by injuring tissue cells as well as bacteria so that in order to prove noninjurious to the patient they have to be diluted to a degree which makes them innocuous to the germs as well.

A comparative study of various antiseptics completed many years ago is summarized below because it is so classic, and the authors (Salle and Lazarus 8) measured the effect of the chemical on tissue cells as well as on bacteria (Table 1).

TABLE 1. Comparison of Action and Efficiency of Various Antiseptics
(After Salle and Lazarus, 8)

Antiseptic	Highest Dilution Showing No Tissue Growth = A	Highest Dilution Showing No Growth of S. aureus = B	Toxity Index = A/B	Phenol Coefficient
Iodine (Lugol's solution)	1-1,800	1-20,000	0.09	308
Hexylresorcinol	1-21,000	1-7,000	3.0	108
Metaphen	1-76,000	1-6,000	12.7	92
Phenol	1-840	1-70	12.0	...
Merthiolate	1-176,400	1-5,000	35.3	70
Mercurochrome	1-10,500	1-40	262.0	0.6

The number expressing the relationship between the dilution inhibitory to cell and to bacterial growth was called the toxicity index. These workers found that iodine in aqueous solution (dilute Lugol's solution) was the only antiseptic more toxic to bacteria than to cells. To this should perhaps be added proflavine and 2:7-diamino acridine, two acridine drugs investigated in England, and found to be the only ones among many tested, which, at a 1:1000 concentration, produced a minimal injury to brain tissue in vivo and the least effect on the metabolism of brain tissue in vitro.

The use of such chemicals in the antisepsis of wounds represents a "test-tube" conception in therapy which is tending more and more to be of historical interest only. The advent of modern chemotherapy with sulfonamides and the many antibiotics has initiated a change toward a more biologic approach. Antibiotics—used singly (9, 10) or in combination (11, 12)—are very effective in the prevention as well as treatment of infections. However, as has been emphasized by Altemeier and associates (13), antibiotics cannot take the place of good surgical technic.

SURGICAL BACTERIOLOGY

Surgical bacteriology may be defined as the application of bacteriological knowledge to the diagnosis and treatment of surgical infections. Most surgical infections are associated with wounds; many, however, develop spontaneously or after slight or indetectable injuries. The latter become surgical because they produce lesions such as abscesses, which require incision and drainage or other surgical procedures.

Classification of Bacteria. Only a few of the many bacteria will be discussed in detail; the following classification is based on the shape, the staining properties, and the anerobic or aerobic properties of growth. Other features of bacteria may be learned by consulting standard bacteriology texts.

CLASSIFICATION OF BACTERIA

Those of most importance to the surgeon are in boldface type
(Modified from Meleney, 14)

CLINICAL OCCURRENCE

I. Aerobic Bacteria
  A. Cocci
    1. Gram-positive
       Streptococci: erysipelas, acute cellulitis, septicemia, acute pyogenic arthritis, osteomyelitis, empyema
       Staphylococci: furuncles, carbuncles, osteomyelitis, septicemia, infected wounds
       Pneumococcus: empyema, peritonitis, acute arthritis
    2. Gram-negative
       Gonococcus (*Neisseria gonorrhoeae*): pelvic disease, urethritis, prostatitis, acute joint infection
       Meningococcus (*Neisseria meningitidis*): meningitis
  B. Bacilli
    1. Gram-positive
       Mycobacterium tuberculosis: infection (bones, joints, meninges, lungs, lymph nodes, peritoneum)
       Bacillus anthracis: anthrax
       Corynebacterium diphtheriae: throat infections, wound infections (very rare)
       Clostridium botulinum: botulism

2. Gram-negative
   - *Escherichia coli:* peritonitis, appendiceal abscess, cystitis
   - *Salmonella typhosa* (*Bacillus typhosus*): typhoid fever, osteomyelitis, perforation of ileum, cholecystitis
   - *Bacillus mucosus capsulatus* (*Klebsiella pneumoniae*): pneumonia, empyema
   - *Proteus vulgaris* (*Bacillus proteus*): secondary invader
   - *Pasteurella tularensis* (*Bacillus tularense*): tularemia
   - *Pseudomonas aeruginosa* (*Bacillus pyocyaneus*): secondary invader
   - *Actinobacillus mallei:* glanders
   - *Haemophilus influenzae:* acute arthritis, empyema
   - *Haemophilus ducreyi:* chancroid
   - *Streptobacillus moniliformis:* rat-bite fever

II. Anaerobic Bacteria

A. Cocci

Streptococci: peritonitis, mouth infections, pelvic infections

B. Bacilli

Clostridium novyi
Clostridium sporogenes
Clostridium histolyticum
Clostridium tetani
Clostridium perfringens (*Bacillus welchii*)
} gas gangrene

C. Spirochetes

Treponema pallidum: syphilis (bones, joints, meninges, skin, etc.)
Treponema pertenue: yaws

III. Higher Bacteria: mycotic organisms (fungi and yeasts)

A. Actinomycetes: actinomycosis, madura foot, nocardiosis
B. *Candida albicans* (*monilia*): moniliasis, diarrhea, thrush
C. *Histoplasma capsulatum:* histoplasmosis
D. *Coccidioides immitis:* coccidiodal granuloma, coccidiosis
E. *Blastomyces dermatitidis:* blastomycosis
F. *Cryptococcus histolyticus* (*Torula histolytica*): torulosis

The bacteria of greatest importance in acute surgical infections are the *pyogenic bacteria.* The term "pyogenic" (pus-forming) is usually applied to all of the following organisms though only the staphylococcus is a typical pus-producer. Moreover, the tubercle bacillus, though not a pyogenic bacterium, may in cold abscesses produce typical thick, creamy pus. Nevertheless, the term is generally used to apply to the staphylococcus, streptococcus, pneumococcus, colon bacillus, and pyocyaneus bacillus. Chemotherapy, especially with the broad-spectrum antibiotics, has a great influence on the pathogenicity of many bacteria as discussed in detail in a separate chapter. Here only the basic features of those mentioned will be described.

The *staphylococcus* exists in at least three forms, the aureus, albus, and citrus; the modifying terms are based on color the colonies produce on culture. Inasmuch as the staphylococcus occurs as a normal inhabitant of the skin, it is sometimes difficult to determine whether the organism isolated from many infections represents a pathogenic strain or an accidental contamination. In general, a staphylococcus which is hemolytic, which is of the aureus type, and which is coagulase-positive is most apt to be pathogenic. Pathogenic staphylococci cause rapid suppuration, forming thick, creamy pus with a sweetish odor which has a tendency to remain localized as an abscess and break through to the outside, eventually healing without difficulty. The favorable outcome which thus followed staphylococcus infections led the ancients to call its pus "laudable." Many, in fact, believed that healing could not occur without the formation of this pus. On the other hand, it is now known that the staphylococcus may incite serious infections such as septicemia and pyemia, and in such cases has been cultivated from the blood stream.

Staphylococci, perhaps more than any other bacteria, have been greatly influenced by the advent of chemotherapy (see Chap. 5). The wide use of penicillin has so attenuated the virulence of many strains that many other strains formerly nonpathogenic and insensitive to penicillin are now producing disease.

The *streptococcus* occurs in several well-known types or strains, i.e., hemolytic, non-

hemolytic, viridans, and anaerobic. Other classifications have divided this organism in other groups depending on sugar fermentation and other properties. It is a normal inhabitant of the oral cavity and vaginal tract and is present in the intestinal contents. When virulent, it is a much more serious invader than the staphylococcus, for it tends to spread and involve wide areas of tissue, causing necrosis without localizing tendencies. Moreover, there is much less tendency to form pus; when pus forms it is usually watery in character though later it becomes thick. Streptococcus is the etiological agent in erysipelas, scarlet fever, acute tonsillitis, and a host of other infections. The anaerobic streptococcus is also a serious invader and is encountered in various pelvic infections, peritonitis, symbiotic infections, and the like. It was the first to be conquered by the sulfonamides early in the modern era of chemotherapy.

The *E. coli* is a normal inhabitant of the lower bowel and, as might be expected, is the main invader after appendiceal infections. It also escapes through the bowel wall in cases of secondary peritonitis from any other such cause as various types of perforation. Pus produced by the organism has an offensive fecal odor and, though in the early stage it is thin, brownish, and watery, it later becomes thicker. Gas may be associated with it. Infections of the gallbladder, liver, and genitourinary tracts are also often due to the *E. coli.*

The *pneumococcus,* though chiefly confined to lung infections, is met with in surgery when such infections are followed by empyema. The pus in such a case, though at first thin, rapidly becomes thick, creamy, and mucoid and contains much clotted fibrin. The pneumococcus may also cause primary peritonitis in children and is the offending organism frequently in acute pyogenic arthritis and sometimes in meningitis. The meningococcus is the invader, however, in epidemic meningitis.

The *Pseudomonas aeruginosa* (*B. pyocyaneus*) is of little pathogenic importance, but is often seen as part of a mixed infection, particularly in large wounds containing necrotic material or over large granulating defects. It betrays its presence by the development of a greenish or bluish discoloration of the discharge and by its peculiar musty odor. It is often associated with *Proteus vulgaris* (*B. proteus*). Various methods have been devised to eliminate these otherwise saprophytic organisms, by means of various bactericidal agents. The most effective way of eliminating them is the removal of necrotic tissue from the wound.

Other bacteria are also important to the surgeon. Mention should be made of anaerobic and microaerophilic organisms, especially, the streptococci which are present in certain puzzling chronic ulcers (see Chap. 8). Spores are also important because they resist ordinary means of antisepsis and may reside in contaminated wounds for years without activity after healing has occurred. The development of the spores into their active vegetative form may occur subsequently after sufficient trauma. Spores occur commonly in tetanus and gas gangrene, which are discussed later. Ordinary pyogenic bacteria may also become dormant under certain special conditions, particularly when they are present in infected compound fractures. Healing may occur, but the organisms remain viable and may set up a severe infection years later if the involved bone is traumatized again for any reason.

Of special importance in the wake of chemotherapy is the conversion of saprophytes to pathogens (see page 85). Pseudomembranous ulcerative colitis may then develop because of the invasion of staphylococci, salmonella, *B. proteus,* and even of monilia.

The Virulence of Bacteria. The disease-producing powers of bacteria vary tremendously. Only a few of the factors will be discussed; they are really to be considered along with the factors influencing the resistance of the body which are described in the next section.

The *strain* or *kind* of bacterium is obviously important. Many of these differences have already been described.

The *number of bacteria* undoubtedly plays a role in virulence. An open wound can ordinarily take care of a certain number of microorganisms without any perceptible increase in the degree of the inflammatory reaction. Wounds which have healed per primam have repeatedly been shown to contain a certain number of bacteria. If the number is too

great, phagocytosis may be ineffective and, by force of numbers alone, the bacteria may set the stage for a real infection.

Foreign bodies and necrotic tissue in a wound contribute to the severity of any infection. This was not generally realized until World War I, during which surgeons of many nations were confronted with millions of wound infections. A clean bullet wound through the thigh, for example, was apt to heal perfectly. Shrapnel wounds, which nearly always contained much foreign material and jagged necrotic tissue, were the most seriously infected. On the other hand, if foreign bodies and devitalized tissue were removed (débridement) within a few hours after the wound was received, the incidence of infection was slight or absent. The medical manuals of all nations finally came to prescribe débridement of such wounds as the primary form of treatment. In acute peritonitis, this influence of necrotic material in increasing virulence has been shown experimentally. Dogs will withstand the injection of large numbers of certain bacteria into the peritoneum without infection; only when bits of sterile agar, muscle, or other foreign bodies are implanted at the same time does a fatal peritonitis follow. In chronic draining sinuses, the role of foreign bodies in maintaining infection is also well known and is described elsewhere in the text.

The time factor in removing foreign bodies and devitalized tissue as a means of reducing the virulence of infections was put into wider practice in World War II and in the Korean conflict. Wounds were seen and treated within an hour or two, i.e., as close to the front line as possible. Better air transportation also helped.

Bacterial symbiosis or *synergism* has also been shown to increase bacterial virulence in certain surgical infections. Many of these observations have been made by Meleney (14). Clinically, such symbiosis undoubtedly explains certain extensive spreading ulcers of the abdominal wall and other parts of the body. The serious nature of human bites which inoculate a mixed group of mouth organisms into the wound may perhaps be explained on this basis. Peritonitis, often caused by a mixed infection, may also owe its high mortality to bacteria acting synergistically, particularly when there is a perforation of the appendix or other viscus.

Chemotherapy, although of great value in the prophylaxis and treatment (15) of infection, has had an adverse effect, as already mentioned, by greatly increasing the virulence of many hitherto nonpathogenic staphylococci (16, 17). This effect on other bacteria is less known but may ultimately prove to be just as important (see page 85).

The Resistance of the Body. The possession of resistance by the patient is often spoken of as his immunity, which may be local or general or both. *Local immunity* depends somewhat on the type of tissue, especially its vascularity. The term is mostly used to describe the local resistance which an area develops after fighting off an infection so that the same organisms can no longer invade at this point at least, though it may still get a foothold in some other part of the body. After a consideration of the available evidence Topley (18) concludes that "it is possible to induce an immunity which is confined to the neighborhood of the treated area, and is not shared by the body as a whole." On the other hand, local immunity may sometimes be decreased, presumably by an increase in local tissue sensitization. This may explain the susceptibility of meat cutters, fish handlers, and milkers to repeated streptococcal cellulitis, often called eryspeloid.

The resistance of the body ordinarily is largely due to a *general immunity,* which declines in the presence of shock (Fine 19) and other abnormal states. The possession of such immunity is specific and resides in the body as a whole, although the protein, particularly the gamma globulin, fraction of the plasma and the cells of the so-called reticuloendothelial system (plus other leukocytic and phagocytic cells), are supposed to be primarily involved in the mechanisms of immunity. A third and important factor in resistance is the protective action of the lymph nodes. The development of leukocytosis during infections is also a manifestation of resistance. The various metabolic responses to infections, wounds, and other conditions have been discussed in detail by Moore and Ball (20). *Natural* (innate) *immunity* refers to resistance inherent or at least obtained in some unknown spontaneous way or congeni-

tally. *Acquired immunity*, on the other hand, is the result of defenses built up in fighting a previous infection. *Artificial immunity* is a similar defense obtained, however, by one of two methods of treatment, i.e., passive or active immunization. Of the two, the latter is especially important in the prevention of tetanus (see page 102).

Malnutrition, especially protein deficiency, often impairs the patient's resistance to an operative load (21) and to at least certain infections. This is certainly true of tuberculosis and probably true of certain pyogenic infections. Cannon (22) has investigated the role of nutritional deficiencies in relation to immunity and has shown clearly, in certain cases at least, how important this factor may be.

Bacterial Diagnosis. Identification of the causative bacterium is most important in all surgical infections, not only in diagnosis and prognosis, but especially in therapy. If specific therapy is indicated or if chemotherapy is to be used, such identification is not only essential but should be made as early as possible. In order to detect bacterial synergism, isolation of more than one organism is obviously necessary. Unfortunately, in the routine methods used in most surgical infections, negative findings are the rule—the report usually comes back "no growth." Such negative information often means failure on the part of the surgeon to observe adequate care in the collection and handling of the infected material. A common error in intraperitoneal infections is to collect only the turbid fluid which escapes as the peritoneum is first opened. It is far better to wait until the source of infection is located and true pus encountered before removing a portion for bacteriological study.

Bacterial diagnosis may be especially important in selecting an effective chemotherapeutic agent. The tests for in vitro sensitivity of bacteria to the many agents now available is discussed elsewhere (see page 78).

Examination of pus is the most direct method of bacterial diagnosis but must be carried out immediately after the abscess is opened. Delay often leads to failure because the lesion is rapidly invaded by secondary organisms. The first and easiest step in the study of pus is to make an appropriately stained smear on a glass slide. The smear may show the nature of the leukocytes, whether polynuclear or mononuclear, as well as bacteria. If the smear shows no bacteria, cultures must be made, preferably under both aerobic and anaerobic conditions. Injection of the pus into guinea pigs or other animals may be important in establishing or ruling out a diagnosis of tuberculosis. For adequate bacteriological examinations it is best to obtain several cubic centimeters of the pus itself. Pus is much more likely to contain organisms if obtained from the *wall* of the abscess. If the amount of pus is small, it is preferable to collect it on a cotton swab which should first be moistened with sterile saline inasmuch as a tiny amount of pus will otherwise be soaked up by the cotton and be lost. Cultures should be made promptly or the material kept in an ice box; if left at room temperature the organisms may die by drying. Some organisms are so sensitive to a change of temperature that they should be cultured immediately when they are removed from the body. In certain cases, part of the tissue lining the abscess should be removed (biopsied) for special bacteriological study. In the case of a lymph node removed for diagnosis, a good plan is to divide it in half, using one for microscopic study and reserving the other half in a sterile, tight, glass container (Petri dish) in the deep freeze for later bacteriological study if necessary.

Blood culture, when positive, is often the only way of identifying the causative organisms in cases where no pus is obtainable. Unfortunately, a blood culture is not always positive even when organisms are present; the power of the blood to rid itself of bacteria is tremendous, at least partially by virtue of the astonishing phagocytic activity of the reticuloendothelial cells which line the blood channels, especially of the lungs, liver, and spleen. Millions of bacteria or tiny foreign particles have been injected into the blood streams of experimental animals only to disappear within a few hours. In general, the greater the number of bacteria found on blood culture, the more serious the infection. Aside from the number of organisms a positive blood culture has considerable prognostic value, as shown on analysis of a large

great, phagocytosis may be ineffective and, by force of numbers alone, the bacteria may set the stage for a real infection.

Foreign bodies and necrotic tissue in a wound contribute to the severity of any infection. This was not generally realized until World War I, during which surgeons of many nations were confronted with millions of wound infections. A clean bullet wound through the thigh, for example, was apt to heal perfectly. Shrapnel wounds, which nearly always contained much foreign material and jagged necrotic tissue, were the most seriously infected. On the other hand, if foreign bodies and devitalized tissue were removed (débridement) within a few hours after the wound was received, the incidence of infection was slight or absent. The medical manuals of all nations finally came to prescribe débridement of such wounds as the primary form of treatment. In acute peritonitis, this influence of necrotic material in increasing virulence has been shown experimentally. Dogs will withstand the injection of large numbers of certain bacteria into the peritoneum without infection; only when bits of sterile agar, muscle, or other foreign bodies are implanted at the same time does a fatal peritonitis follow. In chronic draining sinuses, the role of foreign bodies in maintaining infection is also well known and is described elsewhere in the text.

The time factor in removing foreign bodies and devitalized tissue as a means of reducing the virulence of infections was put into wider practice in World War II and in the Korean conflict. Wounds were seen and treated within an hour or two, i.e., as close to the front line as possible. Better air transportation also helped.

Bacterial symbiosis or *synergism* has also been shown to increase bacterial virulence in certain surgical infections. Many of these observations have been made by Meleney (14). Clinically, such symbiosis undoubtedly explains certain extensive spreading ulcers of the abdominal wall and other parts of the body. The serious nature of human bites which inoculate a mixed group of mouth organisms into the wound may perhaps be explained on this basis. Peritonitis, often caused by a mixed infection, may also owe its high mortality to bacteria acting synergistically, particularly when there is a perforation of the appendix or other viscus.

Chemotherapy, although of great value in the prophylaxis and treatment (15) of infection, has had an adverse effect, as already mentioned, by greatly increasing the virulence of many hitherto nonpathogenic staphylococci (16, 17). This effect on other bacteria is less known but may ultimately prove to be just as important (see page 85).

The Resistance of the Body. The possession of resistance by the patient is often spoken of as his immunity, which may be local or general or both. *Local immunity* depends somewhat on the type of tissue, especially its vascularity. The term is mostly used to describe the local resistance which an area develops after fighting off an infection so that the same organisms can no longer invade at this point at least, though it may still get a foothold in some other part of the body. After a consideration of the available evidence Topley (18) concludes that "it is possible to induce an immunity which is confined to the neighborhood of the treated area, and is not shared by the body as a whole." On the other hand, local immunity may sometimes be decreased, presumably by an increase in local tissue sensitization. This may explain the susceptibility of meat cutters, fish handlers, and milkers to repeated streptococcal cellulitis, often called eryspeloid.

The resistance of the body ordinarily is largely due to a *general immunity*, which declines in the presence of shock (Fine 19) and other abnormal states. The possession of such immunity is specific and resides in the body as a whole, although the protein, particularly the gamma globulin, fraction of the plasma and the cells of the so-called reticulo-endothelial system (plus other leukocytic and phagocytic cells), are supposed to be primarily involved in the mechanisms of immunity. A third and important factor in resistance is the protective action of the lymph nodes. The development of leukocytosis during infections is also a manifestation of resistance. The various metabolic responses to infections, wounds, and other conditions have been discussed in detail by Moore and Ball (20). *Natural (innate) immunity* refers to resistance inherent or at least obtained in some unknown spontaneous way or congeni-

series of streptococcus infections by Keefer, Ingelfinger and Spink (23).

Other methods of bacterial diagnosis are often of considerable importance. Microscopic study of biopsied material may be useful in certain cases, especially in the chronic granulomatous infections, e.g., tuberculosis, actinomycosis, and syphilis. Agglutination tests applied to the blood are very useful in typhoid and tularemia. Doubtless with further study many more infections will become thus more easily detected.

Specific Immune Therapy. Specific therapy with such bacteriologic material as antitoxins have, in general, been of more value in medical than in surgical infections. The use of serums and vaccines must, in any case, be carefully evaluated before adopting them because of the tendency for therapeutic applications of bacteriologic research to far outstrip justifiable indications. *Vaccines* are suspensions of bacteria which have been killed by heat or chemicals and are then injected subcutaneously, intramuscularly, or intravenously. As a prophylactic measure against specific infections to which the patient might be exposed in the near future, vaccines have undoubtedly been responsible for saving many lives (e.g., typhoid prophylaxis). Vaccines were formerly used prophylactically in recurrent staphylococcus infections (furunculosis) in which each focus is assumed to be too mild to instigate sufficient antibody formation. Once an infection has gained a real foothold, the value of vaccine is open to question. The wholesale use of vaccines, once heralded as a cure for practically every infection, has rightfully fallen into desuetude. *Bacteriophage* is responsible for the rather rapid dissolution of certain bacteria in culture on addition of Berkfeld filtrates from other cultures. This remarkable breaking up of bacteria has thus far failed to find a proved place in the treatment of infections, although therapeutic claims have been made and much stimulating research is still going on. *Serums* are used as vehicles for administering specific antibodies, such as antitoxins; usually the serum is that of the horse in which antibodies have been produced by previous treatment with a specific antigen. Such specific therapy is spoken of as passive immunization. The great disadvantage and even danger in the use of serums to confer passive immunity is the possibility of foreign protein reactions. This type of allergic response is produced by certain drugs and chemotherapeutic agents (24). Examples of specific antibodies of value in surgery are largely confined to prophylaxis as in tetanus. However, prophylaxis in tetanus is achieved much more effectively by means of active immunization with the use of tetanus toxoid as described on page 102. This achieved widespread success, particularly during World War II.

The use of repeated blood transfusions for the purpose of carrying specific antibodies, has largely historical interest. Beneficial clinical results from transfusions can be expected only for purposes of correcting sufficiently severe hypoproteinemia and anemia. The extensive use of chemotherapy has also tended to replace the use of specific antibodies in the treatment of infection and will be discussed in a separate chapter.

Recently, *properdin*, an euglobulin in peripheral plasma, has been claimed to play an important part in the defense system against bacterial invaders. Normally present in plasma, it is not an immune body and is nonspecific. Commercial production has not yet been achieved to the extent needed to test its value for general clinical use (see Chapter 14 for details).

Within a year after Domagk's report, Fourneau and his co-workers at the Pasteur Institute in Paris made the amazing discovery that the dye was broken down in the body, yielding paraminobenzine sulfonamide, a white crystalline substance which was really the active chemotherapeutic agent. This compound, whose more popular name is sulfanilamide, had actually been known since 1908 without any suspicion of its potent therapeutic property. Sulfanilamide, moreover, was not protected by manufacturers' patents as was the case of Prontosil, and it therefore came into extensive use rapidly throughout the world. Thus was initiated the new era in chemotherapy. Soon many other varieties of related substances were studied, all of them designated by the generic term of sulfonamide. The idea that the sulfonamides were not actually germicides in the old sense, but owed their effectiveness to their adverse action on the normal metabolism of the invading organism was soon amply confirmed by many observers.

Only those who remember the great virulence of many of the streptococcal infections of the past can appreciate the dramatic nature of this new discovery. Unfortunately, however, the sulfanilamides were ineffective against the staphylococcus. This need was soon met, however, by the discovery and development of penicillin in England. More important than this was the fact that the new agent initiated an entirely new kind of investigation which yielded a quite different type of potent chemotherapeutic drug. Unlike the sulfonamides, these new antibacterial substances were not produced by chemists, at least at first, but could only be obtained through the growth of living microorganisms themselves. For this reason, the new group of drugs was called antibiotics, i.e., products of the biological activity of one organism which were effective against others. Such a phenomenon had actually been known since the time of Pasteur as bacterial antagonism, yet it remained for an English physician and bacteriologist to discover penicillin, a substance resulting from the growth of a mold, which inhibited the growth of staphylococcus. Moreover, it was quite nontoxic even in large doses. Dr. Fleming himself tells the story of the discovery of penicillin (2) as follows:

The story of penicillin has often been told in the last few years. How, in 1928, a mould spore contaminating one of my culture plates at St. Mary's Hospital produced an effect which called for investigation; how I found that this mould—a *Penicillium*—made in its growth a diffusible and very selective anti-bacterial agent which I christened Penicillin; how this substance, unlike the older antiseptics, killed the bacteria but was non-toxic to animals or to human leucocytes; how I failed to concentrate this substance from lack of chemical assistance, so that it was only 10 years afterwards, when chemotherapy of septic infections was a predominant thought in the physician's mind, that Florey and his colleagues at Oxford embarked on a study of antibiotic substances, and succeeded in concentrating penicillin and showing its wonderful therapeutic properties; how this happened at a critical stage of the war, and how they took their information to America and induced the authorities there to produce penicillin on a large scale; how the Americans improved methods of production so that on D day there was enough penicillin for every wounded man who needed it, and how this result was obtained by the closest cooperation between governments, industrialists, scientists and workmen on both sides of the Atlantic without thought of patents or other restrictive measures. Everyone had a near relative in the fighting line and there was the urge to help him, so progress and production went on at an unprecedented pace.

Penicillin is the most powerful chemotherapeutic drug yet introduced. Even when it is diluted 80,000,000 times it will still inhibit the growth of staphylococcus. This is a formidable dilution, but the figure conveys little except a series of many naughts. Suppose we translate it into something concrete. If a drop of water is diluted 80,000,000 times, it would fill over 6,000 whiskey bottles.

Within a decade other microorganisms were found to produce antibiotics. In 1939, Dubos discovered tyrothricin which he obtained from ordinary soil bacteria. Other substances were later found from similar organisms, but their therapeutic application in human disease was handicapped in general by their toxicity when used systemically. However, polymyxin B has been successfully used (3) especially for eradicating the *Pseudomonas aeruginosa* (*B. pyocyaneus*) which is resistant to most other antibiotics.

Much more fruitful has been the group of actinomycetes, first studied by Waksman,

CHEMOTHERAPY IN SURGERY

Historical Survey
General Principles of Chemotherapy
Selection of Chemotherapeutic Agents
Prophylactic Therapy
Definitive Therapy
Untoward Reactions

Chemotherapy in its widest sense refers to the use of specific chemicals to combat any designated disease, including cancer. This does not mean that cancer is necessarily an infection, but that certain chemical agents, which include synthetic compounds, hormones, and enzymes, seem to give promise of halting the growth of certain neoplasms or perhaps even of causing their regression (1). In this chapter, however, only the application of chemotherapy to infections, more specifically to surgical infections, will be discussed. As used currently, chemotherapy in infections includes the use of both the sulfonamides and antibiotic agents. Other terms for these are antimicrobial, anti-infective, antibacterial, and antiviral agents.

HISTORICAL SURVEY

Mercury, used in the sixteenth century in the treatment of syphilis, was probably one of the earliest examples of chemotherapy. During the next century, cinchona bark was found to be curative against malaria even though the active principle *quinine* was not discovered until much later. Aside from the local use of carbolic acid spray by Lister in 1867, there was no further advance for nearly three centuries until 1907 when Paul Ehrlich found that the synthetic drug *atoxyl* was effective against the trypanosome, which was known to cause sleeping sickness. Three years later Ehrlich revolutionized the treatment of syphilis with "606" or salvarsan. Others followed in this path with the discovery of the use of antimony compounds in kala-azar, and emetine in amoebic dysentery. Ehrlich was probably the first to use the term *chemotherapy*. His quest involved studies on thousands of drugs, tested first in the test tube to see if they stained and therefore killed bacteria, later for toxicity in the living organism. This involved systemic empiricism which is still used, but the basic concept is now quite different, as discussed below.

Three decades were to pass before the start, 20 years ago, of the present spectacular era in chemotherapy, which began with the use of sulfanilamide. This new development was really revolutionary because it was based on an entirely new concept which was not obvious at first. Previously, research had been directed at finding drugs which would destroy bacteria in the test tube and yet be nontoxic to the patient's cells; hence the terms germicide and bactericide. The effects of the new chemotherapeutic drugs may be bacteriostatic, bactericidal, or both. The majority of the agents are bacteriostatic, causing interference with the normal metabolism of the various bacteria and thus inhibiting their growth and multiplication. Under these conditions the body's normal defense mechanisms are then able to dispose of the infecting microorganisms.

The first new look in chemotherapy came about quite by accident. Gerhard Domagk, in Germany, in 1935 noted that rats marked with a red dye, Prontosil, did not develop streptococcal infections as did those not so marked. Upon further study he found that this dye was indeed effective in the living animal. The following year this same chemical was shown, by Colebrook and Kenny in England, to be successful in the treatment of human streptococcal puerperal infections.

an increase rather than a decrease in the incidence of civilian wound infections, particularly when the drug was used in conjunction with primary closure of contaminated wounds. It took a long time to relearn the lesson that aseptic technic, meticulous and time-consuming cleanliness, and the mechanical removal of contamination, of dead tissue, and of foreign bodies were important principles in the treatment of such wounds. They are still potent factors in the prevention of infection, without which per primam healing cannot be expected.

In the consideration of the *history of systemic chemotherapy in surgery* we should recall that when the dramatic benefits of the newer chemotherapeutic agents were first called to our attention it appeared that many operations formerly considered necessary to control surgical infections might prove to be unnecessary. This was, in fact, true in such cases as acute osteomyelitis, mastoiditis, and carbuncle (see below). It proved untrue, however, in other surgical infections, notably peritonitis from acute appendicitis. Sulfanilamide alone was first tried in the treatment of acute appendicitis, and other forms of chemotherapy are still erroneously employed in this disease with the idea of avoiding the need for operation. It was soon learned by sad experience that chemotherapy as the sole method of therapy had a real potential danger in this disease because it had no certain influence on the perforation of the infected appendix, which so readily leads to peritonitis. Worse than this, however, the clinical manifestations of infection were masked by this drug, which engendered a false sense of security. Thus peritonitis progressed until it was often too late for the surgeon to remove the cause of the infection and thus prevent a fatal outcome. While chemotherapy has helped to reduce the mortality in perforative appendicitis (see below), it does so only as an adjunct to operative removal of the anatomical cause of the infection.

The advent of chemotherapy influenced surgery in another beneficial way, by permitting the advance of technical frontiers previously feared but now known to be safe. The actual and partly psychologic aid of the new agents gave surgeons courage to use certain technics which reduced complications and eventually led to more rapid convalescence. Three examples may be cited: 1, the early and more radical secondary suture of accidental wounds, discussed in more detail in Chapter 14; 2, the more frequent use of primary intestinal anastomosis, especially of the colon; and 3, the elimination of drainage in many cases of diffuse peritonitis due to perforation of the appendix.

GENERAL PRINCIPLES OF CHEMOTHERAPY

As a result of this historical experience and for other reasons there is now general agreement as to certain principles governing chemotherapy in surgery. The first principle may be expressed by stating that chemotherapy is always an adjunct and not a cure-all in the treatment of the patient. Operation may be and often is urgent on the basis of the indications in each individual case. A second principle applies to the timing of operation in suspected perforative lesions of the gastrointestinal tract, as already discussed above, and in certain deeply seated established infections. Because chemotherapy may obscure the clinical manifestations both local and systemic, operation should be carefully planned in relation to the chemotherapeutic program. In the case of acute appendicitis, chemotherapy should be started after and not before the decision to operate has been made, but well before the anesthetic is given. Timing in operations upon patients with established infections is a little more difficult and is discussed below. A third principle deals with the question of dosage and is based on the idea that a sufficiently large amount of the drug should be given initially and only for as long as necessary, in contrast to the policy of starting with a small dose and increasing it if progress is unsatisfactory. An adequately large dose used for a relatively short period of time reduces the danger of saprophytic bacteria becoming pathogens, and decreases the incidence of acquired resistance by the causative agent to the antibiotics. This principle is especially applicable when operation is indicated for reasons already mentioned. A fourth principle is the importance of early chemotherapy in localized areas of cellulitis in order to avoid suppuration. In such a case,

which led to the discovery, in 1944, of streptomycin and eventually to many other similar antibiotics. In common with the sulfonamides, all of these new substances had the property of altering the metabolism of the invading bacteria so as to prevent them from growing or make them relatively nonvirulent. The rapid historic developments in antibiotics up to 1948 are well described in a monograph by Work and Work (4). The most recent summary of antibiotic therapy is that by Welch and Lewis (5). Much data can also be found in a monograph edited by Dubos (6).

At the present time, the number of antibiotics has increased so tremendously that a dictionary of antibiosis is now available (7). Some of the antibiotics will be discussed in detail later. Two features of this great advance should first be mentioned. In the beginning, each of the new agents seemed to be effective against an increasing number of bacteria, or as commonly expressed, each covered a widening spectrum of bacterial invaders. Unfortunately, a second feature was soon noted; the increasing resistance of bacteria to antibiotics, a phenomenon which naturally greatly decreased and is continuing to further decrease their usefulness. For example, the sensitivity of various staphylococci to penicillin has fallen from 93 to 95 per cent in 1943 to a low level of 12 to 57 per cent in varying reports since then. A similar phenomenon has been observed for the coliform group toward the broad spectrum antibiotics and for the *M. tuberculosis* toward streptomycin (8). This change has been of special importance in the case of the staphylococcus, which has now become so much more virulent that actual epidemics of staphylococcus infection have been described, many of which are unaffected by penicillin or, indeed, by other agents. This is particularly true in the case of personnel and patients living in hospitals, so much so in fact that the term "hospital staphylococcus" has been used to describe this newly developed antibiotic-resistant strain (9, 10). At the same time, more and more patients now show allergic and other reactions to penicillin than ever before, despite the fact that the present product is of greater purity (see below).

The history of local chemotherapy dates from the carbolic acid spray dressings of Lister, through Dakin's solution of World War I, and the local use of sulfanilamide powder in World War II. Though not directly a chemotherapeutic agent, the various proteolytic enzymes (streptokinase, streptodornase, trypsin, plasmin) used for irrigation of infected wounds should also be mentioned at this point because they may be of great benefit in promoting healing by removing nitrogenous debris from the wound and thereby discouraging bacterial growth.

The influence of "in vitro" thinking is still profound, despite the change in emphasis from the test tube to the biological approach toward chemotherapy. There is still a deeply ingrained belief, or rather wishful confidence, in the local antibacterial action of any substance that may be placed into a contaminated or infected wound for this purpose. As a result, countless thousands of dollars have been spent and are still being spent in devising many varieties of chemical substances, including the antibiotics, which may be applied locally for purposes of "ridding the wound of bacteria."

Locally applied chemicals are extensively used throughout the world in the present time as in the past. It should be emphasized, however, that despite its real though limited value, there is a basic fallacy in any attempt to sterilize a contaminated or infected wound in this manner. For one thing, the agent can seldom, if ever, reach all of the crevices and angles of the wound to make contact with the contaminating or invading bacteria. Secondly, the chemotherapeutic agents have no influence on necrotic tissues, inadequately drained deep cavities, and foreign bodies, each of which plays an important part in the progress of a wound infection.

In the early days of chemotherapy this fundamental principle was temporarily forgotten, as exemplified by the mistakes which followed the local use of sulfanilamide on the mass casualties resulting from the attack at Pearl Harbor. Surgeons were too quick to believe in the purported magic of the new powder, which was said to prevent all infection by merely dusting it into and onto all contaminated wounds and burns. What happened was that old, established principles were abandoned. As a result, there followed

TABLE 1. Average Daily Dosage for Chemotherapy

(Aided by New and Nonofficial Remedies, by A.M.A. Council on Pharmacy and Chemistry, J. B. Lippincott, 1957)

Drug	Oral	Parenteral
Sulfadiazine	6–9 gm. (100 mg./kg. initially)	30–50 mg./kg. × 3 or 4 after 100 mg./kg. initially not to exceed 5 gm., as 5% solution IV or as 0.3–0.7% solution subcutaneously
Sulfamerazine	3 gm. (3 or 4 gm. initially)	
Sulfamethazine	4 gm. (100 mg./kg. initially)	
Triple sulfa (equal parts of above)	4 gm. (3 or 4 gm. initially)	
Succinylsulfathiazole (sulfasuxidine)	250 mg./kg. × 6 after same dose initially	
Phthalylsulfathiazole (sulfathalidine)	50–100 mg./kg. × 3–6—not to exceed 8 gm.	
Penicillin		300,000 units (IM or IV) × 3 (or more)
Streptomycin	2 gm.	1 to 4 gm. (IV or IM)
Chlortetracycline HCl (aureomycin)	250 mg. × 4	20 to 25 mg./kg. IV, buffered with sodium glycinate
Oxytetracycline HCl (terramycin)	250 to 500 mg. × 4–8	500 to 1,000 mg. IV
Tetracycline HCl (achromycin)	Same as chlortetracycline	Same
Chloramphenicol (chloromycetin)	250 to 500 mg./kg. × 8 after 50 to 70 mg. initially	1 gm. IM × 2 or 3
Erythromycin (ilatycin)	200 to 500 mg. × 4	250 mg × 4 IV as glucoheptonate (also as lactobionate)
Neomycin	1 gm. per hr. for 4 doses then 1 gm. every 4 hrs. for 24–72 hrs.	Maximum 1 gm. in saline intraperitoneally
Polymyxin B	75–100 mg. × 4	1.5 to 2.5 mg./kg. IM (maximum 200 mg.)
Novobiocin (albamycin)	1,000,000 units × 4	
Viomycin		500 mg. × 2 every third day

often be had within 12 to 24 hours (11). There are, of course, many pitfalls in the collection of material for bacterial diagnosis as already discussed on page 71. These must be avoided, particularly in testing for bacterial sensitivity to antibiotics for mixed infections at least, lest data on secondary invaders be collected and the invading organisms be missed.

In Table 1 the more important drugs are listed along with their oral and parenteral dosage as used in surgical infections. Their application clinically will be discussed under the heading of therapy.

operation may be avoided and the progress of the infection may be reversed, resulting in its spontaneous resolution. The history of acute osteomyelitis illustrates this point very well, and is, therefore, described in detail.

The lifesaving action of penicillin when first used in acute osteomyelitis was almost matched by its equally dramatic influence on the local lesions. Before the days of penicillin, the initial radiologic changes in the bone could be seen in this disease about 5 to 7 days after its onset. Suppuration, long disability, and sequestration followed. The beneficial effects of penicillin upon the bone lesion were first shown when the expected radiologic changes were seen not in a week, but only after two or more weeks. Moreover, the changes were slight, frequently did not progress, or disappeared. It was soon evident that if treatment were started early enough, penicillin had the power to completely prevent sequestration. Even when penicillin was given late, it so inhibited the infection that occasionally a definite demonstrable sequestrum seemed to act as a bone graft and became incorporated into the living bone with little or no surgical procedure. Finally it was found that if penicillin was given in adequate doses within 24 hours of onset there were no radiologic evidences whatever.

To the younger surgeon, failure to show radiologic signs raised the question as to whether the patient actually had osteomyelitis. Such doubts did not occur to experienced surgeons who, in the past, had seen many of these children with characteristic local manifestations go on to show typical radiologic bone changes. Thus it became apparent that, with the early use of penicillin, the value of x-ray in the diagnosis was greatly reduced or even lost. At the present time, therefore, a diagnosis of acute osteomyelitis must be made at the bedside on the basis of the clinical picture and without any corroborating radiologic signs.

The effect on mortality was even more dramatic. Figures at the St. Louis Children's Hospital revealed a death rate from staphylococcic osteomyelitis of 10 to 15 per cent in the years before 1936. During the period of sulfonamide therapy, 1937 to 1942, mortality was still high, 10 deaths among 48 cases. After the introduction of penicillin in 1943 the only two deaths occurred in the first years when the drug was scarce and the dose was inadequate. For example, a child two years old was given a total of only 18,000 units of penicillin. We had not yet learned how effective and important large doses were, and an attempt was made, therefore, to spread the small amount available among as many patients as possible. There have been no deaths since 1944.

SELECTION OF CHEMOTHERAPEUTIC AGENTS

With the vast array of agents now available, it is often difficult to choose the most effective. The trend to utilize an antibiotic having the widest coverage, or even a combination of them, is justified in mixed infection when "combined chemotherapy" is an established practice. The use of more than one agent for the synergistic effect is also justified in certain infections. A popular example is the use of penicillin to destroy the cocci and streptomycin to counteract the gram-negative organisms. In many cases, however, this attitude toward "antibiotics" is based upon the "shotgun" principle of therapy, a principle which in general should be avoided. Selection of a specific antibiotic based upon knowledge of the invading organism or organisms is not only theoretically desirable, but practically feasible in many cases. Only in this way can predictable results be expected, based upon the use of specific agents known to combat specific infections. Such information is sometimes available at once as part of the clinical diagnosis. For example, an acute spreading cellulitis is nearly always due to the hemolytic streptococcus; acute mastitis, furunculosis, carbuncle, and perinephric abscess to the staphylococcus; acute perforative appendicitis to mixed bacterial flora involving the coliform group, streptococci, clostridia, bacteroides, or anaerobic streptococci. Selection of the proper antibiotic can now be made more specific when the organism or organisms are identified from the blood or from the infected tissue or purulent material itself. "In vitro" sensitivity tests of each bacterium against a series of antibiotics can be readily measured. This laboratory procedure is useful when properly done, and the results can

perhaps account for the fact that most of them have proved too toxic for systemic use. *Bacitracin* may, however, be employed as a local agent in specific instances.

More recently *Polymyxin B*, originally called aerosporin, proved of surgical importance as a most effective agent against the *Pseudomonas aeruginosa* (3). However, even this drug must be given with great care and with a local anesthetic agent such as procaine to minimize the pain at the site of the injection.

In the following discussion the various agents will be mentioned first in terms of their prophylactic value and second, in terms of definitive therapy in established infections. It will be apparent, however, that this classification is not always exact and that considerable overlapping will occur in specific types of disease. Untoward reactions will be discussed separately.

PROPHYLACTIC THERAPY

The *local* use of chemotherapy for the prevention of infection in contaminated wounds still has a place whenever considerable delay may occur in definitive therapy. Even war wounds are now handled so promptly after they are sustained that much of the advantage described for local chemotherapy early in World War II has lessened considerably. Nevertheless, any contaminated wound may be helped by local chemotherapy if periods beyond 8 to 12 hours will have lapsed before cleansing and débridement can be carried out, particularly if systemic administration is difficult or impossible. Prophylactic local chemotherapy in wounds has now been largely replaced by systemic administration, for in this way the invading organism can be attacked from the body side which, in general, is much more effective and certain. Indeed, much of the benefit derived from a soluble agent placed in the wound followed its absorption therefrom and the resultant systemic effect. Surgeons are beginning to escape from the test tube concept of contaminated wounds and seem ready to discard or to rely less upon local chemotherapy for the prevention of infection. For systemic chemotherapy, slowly absorbed procaine penicillin G, with or without added streptomycin, was extensively employed in the Korean conflict. However, since absorption was shown to be irregular or even impaired in shock, crystalline penicillin was recommended and was given as an intravenous injection.

The *systemic* use of chemotherapy for the prophylaxis of infection in clean wounds made in the operating room reached its apogee soon after penicillin became available in large quantities and at a moderate cost. This "miracle" drug was soon given after practically every surgical procedure involving an incision or a general anesthetic, starting usually in the immediate postoperative period and often continued until the patient left the hospital. Its routine prophylactic use is now following an ebb course because surgeons are beginning to realize that their blind reliance on it has produced many hazards, as well discussed by Altemeier (8).

For systemic prophylaxis, penicillin and streptomycin are often given simultaneously when contamination has been sustained (e.g., resection of the colon). Originally, the penicillin had to be given every three or four hours, but by changing the vehicle it need not be injected more than two or three times per day (18).

In the case of peritonitis from a perforated appendix, the effect of chemotherapy may be said to be both prophylactic (to prevent further spread of infection during operation) as well as definitive (to combat an established infection). However, since the removal of the source of infection is more important than chemotherapy, the latter can scarcely be called the specific agent for the control of infection as it is, say, in the case of acute osteomyelitis, in which chemotherapy has all but eliminated the need for emergency operation. This does not mean that chemotherapy has not led to a decisive change for the better in peritonitis of appendiceal origin. Mortality from this disease has been cut to less than one-fourth since the advent of chemotherapy, and the morbidity has been all but eliminated. For example, children who were gravely ill with general peritonitis formerly were faced with a mortality above 30 per cent. Such patients can now be operated upon for removal of the appendix, treated with antibiotic therapy, and be ready for discharge from the

Sulfonamides. Although the sulfonamides have little effect on the staphylococcus, their action against streptococcus and against gram-negative organisms is so definite that there is still a place for them, especially since they can be given so readily by mouth and are so inexpensive. The most popular sulfonamides for systemic use are the sulfapyrimadines, i.e., sulfadiazine, sulfamerazine and sulfamethiazine, singly or together. In some infections such as meningitis they are as good as the antibiotics. A recent analysis (12) lists the diseases in which the sulfonamides may be useful, either alone or in combination with the antibiotics. The insoluble sulfonamides are still used for their local action in the gastrointestinal tract but have been somewhat, though not entirely, supplanted by the antibiotics (see below). Research on newer sulfonamides has continued along with extensive investigation in the antibiotic field. One of the most recent and promising of the newer sulfonamides is sulfamethoxypyridazine, which after a single oral dose maintains an effective blood level for over 48 hours and has been followed by no renal complications (13).

Antibiotics. Of all of the various organisms studied, the actinomycetes have yielded the largest number of useful antibiotics. Most of these are tetracyclic, but some are aromatic compounds. All are active against many bacteria, possessing a broad spectrum. All can be given both by mouth and by injection. They are, however, still the most expensive of the antibacterial drugs. When given by mouth most of them are absorbed, thus giving a systemic effect, and also act locally in the gastrointestinal tract to eliminate most of the gastrointestinal bacteria, at least temporarily. In addition they are excreted in the bile and thus also exert an effect in the biliary tract.

Streptomycin (also dihydrostreptomycin), together with penicillin, is moderately effective against mixed infections. It is commonly employed in the treatment of tuberculosis. Mention should be made here of para-amino salicylic acid and of isomers and derivatives of nicotinic acid, such as isoniacid, which have proved of clinical value in the treatment of tuberculosis, particularly when given with streptomycin. Combinations of streptomycin with these agents delay the emergence of resistant strains of the tubercle bacillus and produce better clinical results.

Chlortetracycline (*Aureomycin*), *oxytetracycline* (*Terramycin*), and *chloramphenicol* (*Chloromycetin*) are three of the older antibiotics obtained from actinomycetes. These are called broad-spectrum antibiotics because they are effective against a wide variety of gram-positive organisms (Table 2), as well as the rickettsial, psittacosis, lymphogranuloma, and trachoma group of infections. Unlike the first two, chloramphenicol is an aromatic compound which has been synthesized and is being manufactured for commercial use. It is particularly effective against salmonella and proteus organisms and the *Hemophilus influenzae*. Curiously, few staphylococci have developed resistance to chloramphenicol.

Neomycin has valuable properties in sterilizing the gastrointestinal tract rapidly, often within a period of 24 hours. It is generally considered too toxic for systemic infection, however. It has been used occasionally in the peritoneal cavity as an antibacterial agent in patients with actual or threatened peritonitis (14). Utilized in this manner in large doses, it may produce severe toxic reactions including respiratory arrest.

More recent members of this group are *tetracycline* (achromycin) and *erythromycin*. The latter is of special interest because of its high specificity against staphylococci, which for reasons mentioned above, is particularly important now that penicillin is proving ineffective in more cases (15). *Tetracycline* has been reported (16) as producing much higher blood and tissue levels than oxytetracycline or chlorotetracycline.

Novobrocin (albamycin, cathomycin), another recent entrant into the broad-spectrum field, is particularly effective against the staphylococcus and the proteus organisms (17). The latter is of particular significance in the group of saprophytes which become pathogenic following the use of combined chemotherapy.

Nystatin (Mycostatin) is somewhat effective against the *Candida albicans* (monilia) and apparently against coccidiomycetes.

Antibiotics obtained from soil bacteria, curiously enough, have proved to be polypeptides. This chemical characteristic may

replacement of lost fluids, includes massive, combined, well-chosen antibiotic therapy.

The Production of Delayed Infections by Chemotherapy. One of the unexpected effects of prophylactic chemotherapy has been the postponed or delayed appearance of an infection resulting from contamination, often in an otherwise apparently aseptic and closed incision. Such a delayed infection may be suspected when fever develops as soon as the prophylactic chemotherapy is discontinued. Indeed, it is always important, should chemotherapy be used in this way, to observe the patient for several days, even as long as a week, after the drug has been discontinued. Such delayed infections may be present without fever and be revealed only by swelling of the wound and other local evidences of suppuration. In such cases, the material obtained by separating the affected wound edges should be examined in order to make a bacterial diagnosis and perhaps, if possible, to select a chemotherapeutic agent which is effective for the organisms. The modified chemotherapy should be used in addition to ordinary and simple measures of treatment, particularly the drainage of the abscess. A number of such cases have been studied and critically evaluated (23).

DEFINITIVE THERAPY

The use of chemotherapy as a definitive means of combating established infection shades into its prophylactic use, as already mentioned. Thus, if used sufficiently early during acute cellulitis, many established infections may be stopped in their tracks, so to speak, and thus prevented from producing tissue necrosis and abscess. This not only applies to acute osteomyelitis, as discussed in detail above, but also to acute cellulitis of any type. It is probable, for example, that the therapeutic use of penicillin in the early stages of furunculosis has undoubtedly eliminated the development of many carbuncles.

In most established infections it is desirable, if possible, to obtain some of the purulent material for identification of the organism, as already mentioned above. Thus, unless there is an acute emergency, the selection of or a change to the proper antibiotic agent can be made on the basis of specific information obtained as the result of the identification of the organism and of the results of carefully performed sensitivity tests. When this is impossible, the least that can be done is to determine by smear whether the organism is gram-negative or gram-positive. A most valuable and extensive study of thousands of organisms obtained from surgical infections has been reported by Altemeier and his associates (3) and is summarized in Table 2.

For the treatment of established infections, the sulfonamides cannot be dismissed for reasons already mentioned. However, penicillin and streptomycin still are used extensively and have much to recommend them, especially in patients already confined to the hospital. The various tetracyclic drugs and chloramphenicol are more widely employed, and justifiably so, because they are effective against more organisms and thus applicable when there is a mixed infection. This is not only true in infections originating from the

TABLE 2. Susceptibility Within Bacterial Species

(From Altemeier et al. (3), courtesy of the J.A.M.A.)

	Number of Strains/Susceptibility, Per Cent			
	Penicillin	Chlortetracycline	Chloramphenicol	Oxytetracycline
Hemolytic micrococcus (*Staphylococcus*) *aureus*	768/57	752/67	776/74	729/72
Nonhemolytic micrococcus (*Staphylococcus*) *aureus*	415/57	405/63	418/89	363/69
Hemolytic streptococcus	197/86	192/98	179/97	179/92
Nonhemolytic streptococcus	141/63	132/74	141/92	109/83
Streptococcus viridans	50/80	50/52	58/100	42/95
Escherichia coli	478/0	575/20	586/94	535/92
Proteus group	506/0	488/17	501/79	431/27
Aerobacter aerogenes	170/0	193/72	173/91	153/86
Aerobacter fecalis	21/0	19/68	19/95	14/79

hospital in a little more than the period of time required for an interval appendectomy. This effect, however, cannot be achieved unless the principles outlined are observed, including chemotherapeutic saturation of the tissues of the body before the anesthetic is given and the incision is made.

Prophylactic chemotherapy is indicated in most patients with extensive accidental wounds, including severe burns, seen in civilian as well as in military practice. It is also important in elective operations through contaminated areas such as the gastrointestinal, respiratory (including the oral and pharyngeal cavities), and genitourinary tracts. The latter group is especially important in view of the susceptibility of elderly patients to coliform bacteria after genitourinary operations, as noted in a study of 65 cases (19). This is also true of operations in elderly patients with incipient or actual respiratory disease. In patients of this kind, in whom a postoperative pneumonia is feared, the administration of the antibiotic should really begin before the operation so that the alveolar fluid will contain a therapeutic concentration of the drug during the anesthesia when exudation may begin. It is assumed that the fluid escaping into the alveoli under these conditions will be less likely to lead to postoperative infection and atelectasis if it contains a high concentration of the therapeutic antibiotic. However, the possibility of pneumonitis produced by resistant bacteria under these conditions must be kept in mind.

In an urgent operation performed on any patient in whom there is an unrelated infection elsewhere, such as furuncle or tonsillitis, prophylactic chemotherapy may also be indicated. In patients with pre-existing valvular heart disease, chemotherapy should also be started before operations on the oropharyngeal tract to prevent the development of vegetative endocarditis.

The prophylactic use of various chemotherapeutic agents on gastrointestinal flora in preparation for operation on the colon is of special interest. In the absence of intestinal obstruction and when sufficient time is available, the insoluble sulfonamides, particularly sulfathalidine, are used and will produce temporarily an almost bacteria-free stool in 3 to 5 days. Neomycin achieves a similar effect in 24 to 72 hours, being also scarcely absorbed from the gastrointestinal tract. Streptomycin can be used in the same way. The tetracyclines and chloramphenicol will also produce gastrointestinal antisepsis in three days or less, but, being soluble, will lead to tissue saturation as well. Chemotherapy and evacuation of the large bowel by catharsis or enema should be carefully timed. In the presence of intestinal obstruction or in emergency operations, neomycin is preferable because of its rapid action. The many factors involved in gastrointestinal antisepsis in surgical patients have been critically analyzed by Poth (20).

Prophylactic therapy may also be indicated in two other conditions as the result of recent investigations. The first concerns strangulated intestinal obstruction, where the action of intestinal bacteria on a damaged bowel is now known to produce toxins which are an important factor in the development of peripheral circulatory impairment (21). It is thus important to inhibit or stop this action with adequate chemotherapy before operation in any patient suspected of having intestinal strangulation. Here, too, chemotherapy must not be delayed, but must always be combined with prompt operative intervention.

Chemotherapy is also important in the management of patients in shock associated with severe infections. This condition is generally referred to as "septic shock" and its cause is not necessarily associated with the loss of blood or fluid. This particular type of shock occurring during an infection has been studied in detail by Altemeier and Cole (22), who pointed out several of its diagnostic characteristics. Septic shock should be suspected whenever there is a sudden development of unanticipated circulatory collapse in any patient with fever, particularly when there has been no evident cause such as loss of fluid or hemorrhage. Chemotherapy itself may mask localizing and even systemic manifestations and thus engender a false sense of security in the face of a serious invasion. Other manifestations include failure of shock to respond to the usual methods of replacement therapy, a high leukocyte count above 20,000, and the presence of petechiae, unexplained delirium and ileus. The treatment, in addition to the usual measures aimed at

different observers, but an incidence has been reported as high as 16 per cent. The tremendous increase in the use of penicillin (in 1952, 350 tons were sold) has probably been largely responsible for the increased rate of untoward reactions. The popularity of the longer-acting procaine penicillin has multiplied the hazard since procaine itself has antigenic properties. It is probable that 50 per cent or more of the population of this country has received penicillin at one time or another, unfortunately in the majority of cases with insufficient indications. Since the proportion is constantly increasing, greater numbers of people are becoming sensitive to penicillin. In each patient, therefore, one should specifically ask for a history of penicillin sensitivity, or even whether the patient has previously received this agent. Moreover, anyone with known allergic disease, such as asthma, should be considered to be sensitive until proved otherwise.

In the surgical patient, untoward systemic reactions, particularly fever, are often of great practical importance. Since fever may also be due to the infection for which chemotherapy is being used, the surgeon is often misled as to the need for continuing the drug. When fever persists after other signs of infection seem under control, it is often worthwhile stopping the penicillin, sulfonamide, or other agent to see if the patient will become afebrile. If this occurs, it is likely that the fever has indeed been allergic in nature. A "serum sickness" pattern, which includes the triad of fever, arthralgia, and urticaria (sometimes lymphadenopathy), is, of course, diagnostic of an allergic reaction. Unfortunately, this complication may persist for weeks or months after the drug, including streptomycin and the sulfonamides, is discontinued.

Prevention of untoward reactions is, of course, far better than cure. For this reason penicillin should not be used when the patient is known to be, or likely to be, sensitive thereto, particularly when a suggestive history is obtained, as mentioned above. When allergic manifestations actually occur, changing to another antibiotic is usually indicated, although in mild cases epinephrine or antihistaminic drugs may be used. The more serious manifestations call for cortisone therapy.

Streptomycin. Although used extensively and, in the case of tuberculosis, for long periods of time, streptomycin does have a specific effect of partial or complete paralysis on the eighth nerve in a few patients. This hazard is probably less when dihydrostreptomycin is used. The development of tinnitus or other signs referable to the function of either branch of this nerve should always call for discontinuance of streptomycin and the substitution of some other antibiotic.

Chlortetracyline (Aureomycin), Oxytetracycline (Terramycin), and Tetracycline (Achromycin). These are probably the safest of the antibiotics in terms of provoking allergic reactions, yet they are apt to produce gastrointestinal disturbances, especially diarrhea.

The use of these broad-spectrum antibiotics has led to other more severe gastrointestinal difficulties because of the overgrowth of many microorganisms such as the hemolytic staphylococcus, monilia, the *B. pyocyaneus* (*Pseudomonas aeruginosa*), and *Proteus vulgaris* (*B. proteus*). When the other fecal bacteria have been eliminated by means of chemotherapy, these microorganisms may grow unopposed and assume pathogenic properties even to the production of serious pseudomembranous enterocolitis (26). This mechanism must always be reckoned with whenever broad-spectrum chemotherapy is used in the gastrointestinal tract. The recommended management includes the discontinuation of the antibiotics in use and the administration of other agents known to be effective against the offending organism. When the staphylococcus is responsible, which it often is, erythromycin, chloramphenicol, or other agents may be used, as shown by sensitivity tests, if possible. In other instances, other chemotherapeutic agents may be employed, especially polymyxin-B, and mycostatin against the *B. pyocyaneus* (*Pseudomonas aeruginosa*) and monilia respectively.

Chloramphenicol (Chloromycetin). This is the first naturally occurring antibiotic containing a benzine ring with a free nitro group. It was thus expected to be more antigenic than other antibiotics obtained from the growth of actinomycetes. While a number of cases of agranulocytosis and aplastic anemia were reported early, later experience seems to indicate that the drug is as safe as the other broad-spectrum agents. It is now being used

gastrointestinal tract, but also in external wounds which have been secondarily invaded by many contaminating organisms. While chemotherapy may be all that is necessary in a few established infections, such operative procedures as incision and drainage of abscesses, closure of perforations, removal of necrotic tissue and foreign bodies, plastic repair or closure of wounds, skin grafting, and closure of fistulas or anastomoses are usually necessary and must be carried out at an appropriate time. The common mistake is to wait too long for such operations, which should really be carried out as soon as possible after the infection is localized or has been brought under control, as the case may be. Delay often permits sensitive organisms to develop resistance to the agent and saprophytes to become pathogenic.

UNTOWARD REACTIONS

The indiscrimate use of antibiotics, which started soon after their introduction and unfortunately still continues, is undoubtedly responsible for the large number of unfavorable reactions now encountered. It cannot be emphasized too strongly that any drug, including antibiotics, should be used only when definitely indicated. The complacent, uncritical administration of any material to a healthy or sick patient imposes definite responsibilities upon the physician and surgeon (24). This philosophy has already been discussed in the section on blood transfusions. This does not mean that these effective chemotherapeutic agents should be withheld when they are really needed, but it does mean that they should not be employed unless there is a definite indication. Moreover, the dosage should be adequate but not excessive, and should not be continued indefinitely after a favorable response has been achieved, or after it has become apparent that such a result cannot be achieved. In the following discussion it will be apparent that many untoward reactions are allergic, due to hypersensitivity of the body to the antigenic action of the drug. This state may be produced by the absorption of small doses of the drug even from an ointment applied locally. An excellent short monograph by Alexander (25) describes the nature and clinical significance of many of such reactions. Much of the following data was culled therefrom. On the other hand, many untoward reactions can be described merely as "toxic" and some due to specific mechanisms which will be described.

Sulfonamides. The sulfonamides have chemical characteristics, such as a benzine ring with the free NH_2 group in the para position, which have long been known to possess haptenic (antigenic) properties. Such drugs tend to produce allergic reactions usually when given for the second time in therapeutic doses after an appropriate interval. Nevertheless, allergic manifestations such as skin eruptions from the sulfonamides are seldom serious and certainly not more frequent than 5 per cent. Sulfanilamide itself was much more likely to produce side effects, but is seldom if ever used at the present time and hence is not discussed. More serious allergic or "toxic" manifestations such as hepatic damage, periarteritis nodosum, and nephrosis, though quite rare, are important because of their high mortality. Fever, though also rare, leads to clinical difficulties similar to those encountered with penicillin, which is discussed below. A specific type of rênal damage associated with sulfa therapy is due to the precipitation of the acetyl derivatives of these drugs in the renal tubules. Fortunately this problem can be readily solved because the acetyl derivative of each of the sulfonamides is different and independent of the others. Thus the likelihood of precipitation can be reduced by giving a much smaller dose of each of three or more different, selected sulfonamides and by maintaining an adequate fluid intake and urinary output. Fortunately their therapeutic action and blood levels are additive.

Penicillin. When first introduced, penicillin, even though relatively impure as compared with present products, seldom produced an untoward reaction, even when given in daily doses up to several million units a day. However, by 1951, six fatalities due to anaphylactic shock, the most severe manifestation of allergy, were reported. Many more have occurred since then, in fact with increasing and alarming frequency. Moreover, the incidence of the more common allergic skin eruptions, such as erythema and urticaria, though fortunately seldom of clinical importance, has been rising sharply. The figure varies with

6

ACUTE SURGICAL INFECTIONS

Surgeons have long been arbiters in the management of those infections arising as a complication of injury or requiring surgical incision, usually for the drainage of pus, as a feature of management. This is the background for the identification of "surgical" infections; and this chapter is largely concerned with the features and basic principles of pyogenic infection and suppuration.

Shortly after the introduction of sulfonamides and, more especially, penicillin, it was apparent that the gravity of surgical infections had been remarkably and favorably decreased. This remains true for those infections for which *bactericidal* drugs are available, as in the case of the hemolytic streptococcus. On the other hand, there has developed an unstable ecology as regards those bacterial pathogens originally susceptible to drugs that were chiefly *bacteriostatic.* Drug-resistant staphylococci, *Proteus vulgaris* (*B. proteus*), and pseudomonas (pyocyaneus), initially identified in the course of inadequately treated infections, are now being recognized as primary pathogens or as the responsible agents in hospital epidemics of wound suppuration (1). Although antibacterial therapy has revolutionized the technics of management of infections in general, the complexities and final impact of drug treatment have not yet been fully evaluated. There has been no change in the early manifestations of a potentially serious infection or in the basic principles of wound management or surgical drainage of pus. It is recognized that antibacterial therapy may mask the systemic manifestations while the local lesion progresses, and it is axiomatic that chemotherapy cannot obviate the necessity for the surgical evacuation of pus or the excision of tissue devitalized by injury or sepsis. This often creates a dilemma calling for mature judgment on the part of the surgeon. Some abscesses may be treated primarily by incision and drainage without chemotherapy, whereas surgical manipulation of other abscesses may precipitate bacteremia and demand chemotherapy to prevent the development of metastatic abscesses. There are other complications of antibacterial therapy apart from toxic or allergic reactions. Alteration of the normal body flora may permit the overgrowth of yeasts or locally necrotizing saprophytes. Most of these considerations are presented in more detail in the chapter on chemotherapy, but it should be remembered that they apply to the suppurative infections discussed here.

PATHOGENESIS

It is probably true that most primary surgical infections are due to pyogenic cocci, either the beta hemolytic streptococcus or the coagulase-positive micrococcus (staphylococcus). These organisms gain entry to the body through sweat glands, hair follicles, or wounds of the skin or mucous membrane. Once the bacteria have penetrated the protective integument, the subsequent course of events is determined by the virulence of the bacteria, the resistance of the host, and the size of the inoculum (Koch's postulates). For the pyogenic cocci, the somewhat nebulous factor of virulence may be manifest in terms of intense local necrosis of tissue, erysipelas or scarlet fever, or rapidly invasive spread through previously normal tissues. These

more and more, especially since it is effective against a greater number of organisms than other agents (see Table 2), and thus it is less likely to permit saprophytes to become pathogenic. Many of the salmonella group, especially *S. typhosa*, are more sensitive to chloramphenicol than to the other tetracyclic antibiotics. It is also more effective in meningitis than other agents with the possible exception of sulfonamides.

Neomycin. Though not in use very long, neomycin has thus far shown no allergic manifestations. Its rapid action against fecal organisms probably accounts for its relative freedom from the untoward effects of aureomycin and terramycin mentioned above.

Fig. 1. Acute cellulitis of the right orbit which subsided spontaneously with conservative care. A, at the onset of the swelling; B, nine days later. The primary cause of the cellulitis was a right antral infection which was drained intranasally.

Cellulitis or bacterial *inflammation* consists of local manifestations which are similar to those of nonbacterial inflammation as already described, but so much more pronounced and severe that seldom is there any difficulty in differentiating the two. Subjectively, the patient will usually complain of pain, redness, swelling, and disability. The pain is usually more severe in such sensitive tissue as at the tips of the fingers and such sites as the thick skin at the back of the neck, where swelling results in rapid increase of tension. In such lax tissues as those of the face, pain is apt to be less severe but swelling more evident. Often there is also a throbbing which, with the pain, is aggravated by a dependent position of the inflamed part.

On inspection one sees first the swelling and redness and may feel the heat radiating from the area, all caused by the hyperemia and increased blood flow and exudation. The *redness* is of a fiery color, most intense at the portal of entry, and fading off gradually into normal surrounding skin. The *swelling* often coincides with the redness. Swelling well beyond the area of cellulitis, not red or tender, is due to edema and is observed especially in infections of the hand and face. Should the swelling be so intense as to impair the arterial supply, the part becomes blanched and eventually necrotic. On palpation one can demonstrate *tenderness;* i.e., induced pain or pain elicited on pressure. Such palpation may be justified in order to detect *point tenderness,* which often reveals the probable location of a deep infection, that as yet has produced no changes on the surface of the skin, or which determines the probable site of suppuration in diffuse cellulitis.

Lymphangitis. The lymphatics are invaded early in the course of an invasive infection (Fig. 2). If the channels themselves become inflamed they are evident clinically as red streaks extending toward the regional lymph nodes. Such red streaks are spoken of as tubular *lymphangitis.* Similar involvement of the more superficial lymphatics of the skin may be apparent as a network of red streaks and is known as reticular *lymphangitis.* These lymphatics are tender and the local swelling may be outlined by palpation after application of an ointment to the skin to reduce tactile friction.

Lymphadenitis. The regional lymph nodes are almost always involved in the course of an infection and become palpably enlarged.

manifestations reflect the variable biologic activities of these cocci and require further explanation.

1. *The locally necrotizing action* is due to proteolytic enzymes capable of destroying tissue. The most important of these is collagenase, usually identified in the laboratory by gelatin liquefaction. It is these enzymes that break down tissue to the essential metabolites necessary for bacterial multiplication within the body. Inasmuch as devitalized tissue is generally more vulnerable than living tissue to such proteolysis, the presence of dead tissue favors a more rapid growth of bacteria and assures a more severe infection. It is sometimes forgotten that Pasteur's initial interest in bacteria related to a study of these enzymes and that he defined aerobic proteolysis as fermentation and anaerobic proteolysis as putrefaction. The foul odor of intermediary amides and amines identifies anaerobic proteolysis and distinguishes it from aerobic proteolysis wherein protein is reduced to odorless carbon dioxide, nitrogen, and water. The enzyme systems of the pyogenic cocci are aerobic and especially effective against such collagen-rich tissues as skin, fascia, and tendon to produce liquefaction (suppuration).

2. *The erysipelas or scarlet fever* reaction is due to the production of erythrogenic exotoxin. This toxin is associated primarily with the hemolytic streptococcus, but antigenically indistinguishable erythrogenic toxin is also produced by the staphylococcus. The erythrogenic toxin produces a scarlatiniform rash and sustained fever. When the primary infection is extrapharyngeal and the rash is diffuse, the term "surgical scarlet fever" may be applied. For localized erythemas without cutaneous pigmentation (as demonstrated by complete blanching with pressure applied by a glass slide) and in direct continuity with the local infection, the term "erysipelas" is applicable. The presence of scarlatina or erysipelas is important primarily because the erythrogenic toxin enhances the tissue invasiveness of the pyogenic cocci.

3. *Tissue invasiveness* is dependent upon the capacity of bacteria to invade and spread through living tissues; it is a complex and still incompletely understood phenomenon. The usual response to the injection of such a locally necrotizing substance as turpentine is the process of inflammatory fixation with characteristics of capillary and lymphatic thrombosis around the area of tissue destruction. In the case of the pyogenic cocci, this response is altered. The beta hemolytic streptococci produce a fibrinolysin capable of activating plasminogen to plasmin and promoting dissolution of the plasma thrombus within the lymphatics and allowing the bacteria access to the lymph stream. The staphylococci, on the other hand, appear to intensify the thrombotic process with the result that septic emboli become blood-borne to create metastatic abscesses. Both of these processes intensify the extent and gravity of the local lesion and foster bacterial invasion of the blood stream. This latter complication is known as *bacteremia,* but it is usually reserved in clinical usage for relatively asymptomatic phases of blood-stream invasion. Symptomatic bacteremia (staphylococcemia, streptococcemia) is known as *septicemia,* a word introduced before the discovery of bacteria to identify an experimental disease produced in healthy sheep by injecting them with the blood of animals dying from anthrax. The term *pyemia* is usually reserved for bacteremias of great intensity complicating multiple metastatic abscesses. The lay term is "blood poisoning."

The local and systemic effects of acute surgical infections, including paths of extension, general principles of treatment, and prognosis will be described in that order. The deeper and more regional infections are discussed elsewhere under each specific region or system.

THE LOCAL LESION

Cellulitis. Bacterial invasion at the portal of entry usually produces an area of inflammation, called "cellulitis" (Fig. 1). This is to be distinguished from suppuration, or the formation of pus, which often but not always follows. The distinction between cellulitis and suppuration is important therapeutically because any incision into an area of cellulitis is rarely of value when no pus is present and may actually lead to *dangerous spread* of the infection. Conversely, when pus is present, incision and drainage should, with few exceptions, be promptly carried out.

Fig. 3. The use of two fingers in eliciting fluctuation in a swelling containing fluid. (From Homans. Textbook of Surgery, Charles C Thomas.)

tenderness is an important sign of suppuration when fluctuation is difficult to elicit; e.g., in many infections of the hand and in very small areas of inflammation where it is mechanically impossible to test for fluctuation. In such cases, the gradual narrowing of the zone of tenderness on successive examinations may be of decisive importance as an indication that pus has formed. Point tenderness is also valuable in such deep infections as those of the ischiorectal space or the deep tissue of the thigh or back. *Aspiration* may be advisable in detecting pus in large abscesses, especially when the depth or location of the lesion makes fluctuation or point tenderness difficult to elicit. Aspiration may also be used in other situations where questionable fluctuation exists or cannot be detected; e.g., in empyema thoracis and pyogenic arthritis. If the pus is thick, aspiration may fail unless a large-bore needle is used. Obviously aspiration is contraindicated when it may result in injury to vital or important adjacent structures.

TYPES OF SUPPURATION

Suppuration may take a variety of forms. A few of the types occurring on the surface of the body are described under the following headings:

Simple Abscess. These infections usually follow puncture wounds of the skin, but the initial injury may have been so trivial as to be forgotten. Abscesses in the axilla, groin, and neck are commonly due to suppurative lymphadenitis; in the upper part of the neck dental infections are commonly the cause of abscesses (Fig. 4). Incisional treatment for drainage has already been outlined.

Furuncle. The common boil has a definite anatomic location in the hair follicle and is always caused by the staphylococcus (Fig. 5). It is not always clear how and why this normal inhabitant of the skin suddenly invades the wall of the follicle. Patients with diabetes or Cushing's syndrome are especially subject to furunculosis. The sweat, which normally contains complex fatty acids, is usually bactericidal, but this quality may be lost without apparent explanation or in consequence of profuse diaphoresis. This latter effect is commonly used to explain the summer prevalence of furunculosis.

The initial symptom of a furuncle is pruritus, suggesting an insect bite. Once the staphylococci get a foothold, the process extends beyond the wall of the follicle as an area of cellulitis, which quickly softens into an abscess. The demarcated and necrotic remnant of the follicle in the center may resist digestion and remain as a stout plug, called the core, requiring extrusion or removal. In small furuncles, seen early, suppuration may often be prevented and the infection absorbed by covering the area with thick adhesive plaster. This simple procedure is probably effective because it prevents radiation of heat and thus maintains local hyperemia, and also because it insures local rest and prevents further irritation by clothing or the patient's fingers.

Recurrent furuncles, or *furunculosis,* were often the despair of patient and physician alike. Although not always successful, the use of anionic skin detergents, rather than soap, re-establishes the bactericidal protection of the skin and should be prescribed. Effective and appropriately selected antibacterial therapy is occasionally necessary. Diabetes

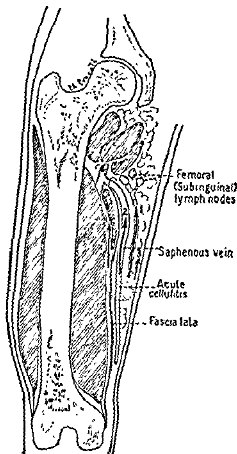

Fig. 2. Three paths of extension of a cellulitis located, for example, on the inner side of the thigh. 1, by lymphatic spread; 2, by venous channels; and 3, by direct extension into the deeper fascial planes or subcutaneously.

When these are tender from rapid swelling, it is presumed they have been invaded by bacteria. It is customary to designate this as septic lymphadenitis. More commonly with staphylococcal infections, the lymph nodes become swollen but not tender and are regarded as inflammatory rather than septic.

Erysipelas. Often in association with streptococcal cellulitis, and occasionally with staphylococcal cellulitis, there is an associated erythematous edema of the skin with palpable borders extending for a considerable distance from the obvious area of cellulitis. This erythema is bright red and blanches completely on pressure, in contradistinction to the bronze erysipelas of anerobic cellulitis. The skin usually desquamates over the involved area during convalescence. These changes are attributable to the erythrogenic toxin and are not usually given special identity in the course of a subsequently suppurative lesion. They may occur, however, without other manifestations, and the infection is then classified as erysipelas. The common erysipelatous lesion about the face, when streptococci enter minor abrasions from the use of spectacles, etc., has a characteristically butterfly appearance. Of more frequent occurrence is the recurrent erysipelas of the lymphedematous extremity, particularly the postphlebitic leg. Skin biopsies almost regularly yield sterile cultures. This has found experimental explanation in the fact that the skin changes follow by some hours the initial invasion by bacteria and the destruction of these bacteria by the host (2). A more detailed discussion of erysipelas will be found *in the following chapter.*

Suppuration (Abscess Formation). Cellulitis may subside uneventfully without, but more frequently with, an appropriately selected and effective antibacterial drug. However, if in the course of the cellulitis there is tissue destruction, its ultimate septic decomposition is assured. Antibacterial therapy rarely, if ever, destroys the bacteria within such a *nidus* of devitalized tissue. The liquefied mass of bacteria, dead leukocytes, exudate, and necrotic tissue is known as pus and the process of liquefaction is known as suppuration. The abscess is identified by the evidence of liquefaction and softening in the center of the lesion. Many other terms are used to identify this process of suppuration and abscess formation; e.g., localization, coming to a head, pointing, walling off, and developing a pyogenic membrane.

The formed abscess develops an internal pressure equivalent to capillary blood pressure and independent of the osmolality of its pus (3). It thus becomes clinically demonstrable by *fluctuation.* Fluctuation is the sensation given to the palpating fingers by any localized collection of fluid, provided it is present under limited tension. One finger compresses the fluid and transmits the impulse to the other, stationary, examining finger (Fig. 3). Lipomas, cysts, or other tumefactions may be so soft as to impart a sense of fluctuation, but cause no difficulty in differentiation in the absence of inflammation. Suppuration may, of course, be evident on mere inspection when the pus has reached the surface and shows through the skin. *Point*

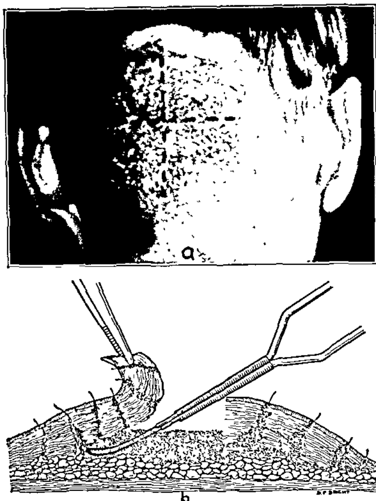

Fig. 6. Carbuncle of the neck: a, the patient is a 55-year-old machinist who first noted a tiny infection of a hair follicle two weeks previously, which spread to its present size. The carbuncle is located higher in the neck in this patient than usual. *The dotted line indicates the lines of incision. Healing was complete* after many weeks; b, diagram of a cross section of a carbuncle showing the multiple "heads" and extension below the derma and involvement of the subcutaneous fat. The proper method of undermining the edges of the skin with a cautery in order to achieve adequate drainage is also indicated. Local and systemic use of penicillin greatly aids healing.

Collar-Button Abscess. Known also as a dumbbell abscess, this infection consists really of two abscesses connected by a tiny communication through some such tough structure as derma or fascia. One of the cavities is superficial and the other is deep. The deep abscess is harder to detect, yet recognition is essential for adequate drainage. Collar-button abscess is especially common in the hand, where a deep palmar abscess may break through a tiny opening in the deep fascia and present as a subcutaneous lesion in the web of the fingers on the dorsal aspect. Persistence of drainage after incision of any superficial abscess should arouse suspicion of a deeper pocket. Such a pocket may often be outlined *radiographically after injection of* a radiopaque fluid.

Carbuncle. A carbuncle may be described as a series of collar-button abscesses whose deeper pockets communicate while the superficial abscesses are separate (Fig. 6). The infection may start as a simple boil, or furuncle, which breaks into and extends along loose areolar and fatty subcutaneous tissue, coming to the surface irregularly along tiny channels described by J. C. Warren as "columnae adiposae." The tough derma in the

Fig. 4. A subcutaneous abscess of the neck. This abscess (under the mandible) resulted from an acute dento-alveolar abscess which ruptured through the tissue about the jaw but did not enter the floor of the mouth or the deep cervical tissue. Incision and drainage were followed by satisfactory healing.

A

B

Fig. 5. A, large furuncle of the face near the hair line; B, an acute *furuncle of three days' duration which, because of its location, represents a dangerous type of infection. Rest and local heat were applied* with spontaneous drainage and rapid healing. Incision in this type of infection is hazardous (see Fig. 8).

should always be *suspected* and appropriately treated if diagnosed.

To be distinguished from furunculosis is *suppurative hydradenitis*, an infection of the sex-linked sweat glands found in the axilla, perineum, and in the inframammary fold of the female breast. Organisms other than the staphylococcus are often present, but skin hygiene with anionic detergents is the initial procedure of choice. Occasionally it may be necessary to excise this entire segment of the skin.

veins may extend into the cavernous sinus. Similar emissary veins are present in the frontal, mastoid, and occipital areas and communicate with the superior longitudinal or lateral venous sinuses within the skull.

The clinical manifestations of septicemia are often so clear as to permit a bedside diagnosis. The important aspects are listed in this order:

1. A *chill* often announces the entrance of particulate foreign protein, in this case the bacteria, into the blood stream. The sensation of cold is pronounced and, in its more severe form, causes muscular contractions so that the patient shivers and the teeth chatter. There is peripheral vasoconstriction so that the extremities become cold and body temperature rises.

2. *Fever* invariably accompanies systemic infection. In the absence of septicemia, it is usually sustained with a mild diurnal variation. In bacteremic infections there are regular and irregular swings of the temperature curve with readings of 40° to 42° C. (104° to 107° F.) as peak values (Chart 1). Such a fever is referred to as *septic* or *spiked*, and marked elevations of temperature are associated with chills. There is evidence that fever up to 40° C. (104° F.) may reflect the accelerated metabolism of the defense reaction and may even be important to it. It is absent, for example, in some of the very severe infections that pursue a fulminant course to the death of the patient. However, fever above 40° C. (104° F.) is, in itself, deleterious and may prove fatal. Because moderate fever may serve a useful purpose, antipyretics and sponge baths are reserved for the comfort of a patient or the treatment of true hyperpyrexia.

3. *Prostration* in septicemia may vary from a feeling of general malaise to complete asthenia. Occasionally the collapse is so complete that there is hypotension or severe shock ("septic shock"). Characteristically, blood transfusion must be supplemented with other measures if the blood pressure is to be restored.

4. *Leukocytosis* is usually present in a range of 13,000 to 20,000 cells per cubic millimeter. The "leukocytosis promoting factor" of Menkin (7) is of such molecular size as to suggest that an observed leukocytosis necessarily implies its intravascular synthesis. Hence, the leukocytosis should suggest the presence of a septic phlebitis. The differential count is often characteristic with a "shift to the left" and disappearance of eosinophils due to the stress effect. In severe infections, there may be a normal or low leukocyte count with such a severe left shift that it is designated as a leukemoid reaction. In agranulocytosis or fulminating infections, the failure of development of a polymorphonuclear leukocytosis is of ominous import.

5. *Blood culture* should be positive at some time in all cases with a diagnosis of septicemia. Repeated cultures with special media are sometimes necessary. Meticulous technic is essential lest a contaminant lead to a false positive with obvious confusion as to diagnosis and effective chemotherapy.

6. The *sensorium* is often disturbed, frequently on the basis of translocation of the extracellular fluid volume with electrolyte imbalance. The patient may be apathetic and listless or he may be apprehensive or delirious. Generalized hyperesthesia of the skin is frequently present. A prominent and frustrating symptom of chronic infection is the loss of morale and desire to get well. This late consequence of infection frequently responds to small doses of testosterone, if the patient is an adult male.

7. *Digestive symptoms* are especially frequent in children, in whom nausea and vomiting may be premonitory symptoms. Anorexia is common to all ages and may require special nutritional care to minimize wasting of body reservoirs.

8. *Metastatic foci* may result from either lymphatic or venous extension. Lymph-node abscesses occur in the channel of drainage. Blood-borne metastases also follow the pattern of proximate infarction with the lung as the primary target of the systemic venous drainage. Early evidence of septic embolism of the lung consists of tachypnea, mild diffuse chest pain, and elevated venous pressure. Productive cough and rales are later developments. Pneumonitis or empyema thoracis are obvious complications of this pattern of metastasis, but lung abscess, pyopneumothorax, and major hemoptysis are also possible. Bacteria may pass through the capillary filter of

neck and back, where carbuncles most frequently occur, resists digestion so effectively that pus never drains adequately.

Before antibacterial drugs were available, carbuncles tended to drain for weeks, often involving more and more tissue and giving a necrotic appearance to the skin. The pain was usually severe, but the systemic manifestations were largely those of fever. The usual treatment was by cruciate incision through the tough derma into the deeper abscess pocket. Less commonly, the lesion was excised with knife or cautery and the wound subsequently skin grafted.

The early use of an effective antibiotic drug has made carbuncle a rarity. The potential destructiveness of these lesions and the increasing drug resistance of staphylococci make it mandatory to test the sensitivity of the infecting organism in every instance. Coexisting diabetes should always be remembered as a possibility.

Suppurative Fasciitis. Although penicillin regularly effects the complete resolution of streptococcal cellulitis, in elderly patients with diabetes and/or arteriosclerosis and cellulitis of the extremity, the lesion frequently fails to subside completely. The important residual is an area of induration and tenderness along a fascial plane. As long as the patient receives penicillin, complaints and systemic manifestations are minimal. However, if the patient is discharged prematurely, there develops an extensive liquefaction of the fascial plane that soon erodes the derma at one or more points to create draining sinuses. This late picture is reminiscent of the hemolytic streptococcus gangrene of prepenicillin days.

It is now established that these areas of residual induration are most appropriately treated by longitudinal incision, evacuation of the mucoid pus, and delayed suture, some three to five days later, under the protective influence of continued penicillin therapy.

SYSTEMIC EFFECTS: SEPTICEMIA

Bacteria may enter the blood stream by way of the lymphatics or the veins. There is good ground for believing that an initial bacteremia of transient and asymptomatic nature may complicate the squeezing of a boil or the extraction of teeth. Such an episode, unrecognized initially, may permit the implantation of bacteria in vulnerable organs or on diseased heart valves to initiate a later septicemia long after the peripheral lesion is healed or forgotten.

Lymphatic extension to the blood stream is nearly always associated with lymphangitis and septic lymphadenitis. The resultant septicemia is characterized by the isolation of invasive bacteria of high virulence in relatively constant numbers per milliliter of blood. The lymphatic pathway is a common route for anthrax organisms, plague bacilli, and, less commonly, hemolytic streptococci. The peripheral lesion is one of cellulitis; the onset is abrupt, and the course fulminant with early peripheral vascular collapse.

Venous extension to the blood stream—as was recognized by John Hunter, Virchow, Welch, and, more recently, Pappenheimer (5)—is the more frequent mechanism of septicemia. Serial blood cultures reveal marked variation in the numbers of bacteria per milliliter of blood. Occasionally there may be actual inflammation of a vein with the characteristic swelling, heat, redness, and tenderness of *septic phlebitis*. Often such an inflamed vein becomes thrombosed, producing *thrombophlebitis*. If a major vein is involved, there is the hazard of fatal pulmonary embolism. More often, detached fragments of the infected thrombus contaminate the blood stream to become implanted elsewhere and initiate secondary, or metastatic, abscesses. The location of the metastatic abscesses frequently identifies the primary focus. The peripheral venous system is suspected when the lungs show septic infarcts of comparable development, but the right side of the heart should be indicted when the lungs show abscesses as well as fresh areas of pneumonitis. Peripheral embolization may result from either left heart endocarditis or suppurative pneumonia. The kidneys, brain, red marrow of bones, lungs, and heart are especially vulnerable to metastatic abscess formation in staphylococcemia (6).

Furuncles or carbuncles of the face and head carry a special hazard of septic phlebitis. An area including the upper lip and the nose is known as the "dangerous triangle" because septic phlebitis of the nasolabial and angular

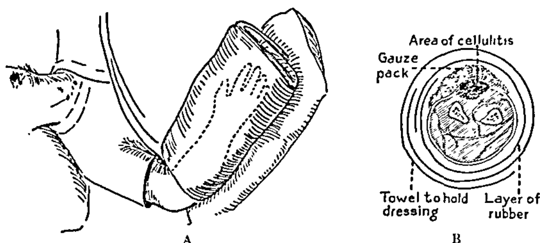

Fig. 7. Elevation and hot wet packs in the treatment of acute cellulitis. A, proper angle of elevation on a pillow; B, diagram of the various layers constituting a wet pack.

tissue, irrigation to remove dirt, foreign bodies, and blood clots, and delayed sutures (Chapter 14). Tetanus prophylaxis with toxoid or antitoxin and streptococcus prophylaxis with systemic penicillin are proper adjunctive therapy.

The treatment of an established infection requires additional measures. These may be discussed under the headings of 1. local measures for cellulitis and suppuration and 2. general measures aimed at the treatment of septicemia.

Local Measures. 1. *Nonoperative Therapy. Rest* not only reduces movement of the affected part and thus minimizes pain, but, more importantly, immobilization reduces the danger of extension of the infection into lymphatics and adjacent tissue spaces. *Elevation* of the part is advisable to promote the local circulation by aiding lymph and venous flow; swelling is also lessened and with it pain. An ordinary muslin sling is the simplest way to put the distal upper extremity at rest. With the patient in bed, elevation of the extremity on a pillow is just as effective. Splints are useful to immobilize fingers or hands and can be applied in addition to the use of the sling. Restriction of ordinary activities may be necessary to insure adequate local rest. Infections of the lower extremities call for confinement to a chair; of the trunk, rest in bed. In no case, of course, should the sling or splint be applied so as to cause pressure sufficient to impair the local circulation. *Relief of pain* is achieved to a considerable degree by rest and immobilization; heat may add to the patient's comfort; cold sometimes does, but has its possible dangers. Drugs such as aspirin, codein, and morphia are to be used freely as indicated during the few hours or days when the pain is most acute. *Local application of heat* aids in the favorable outcome of the inflammatory process whether it is abortion or localization with abscess formation (Fig. 7). It increases the *active hyperemia,* which means a greater blood flow, increased metabolism, and greater leukocytic activity, thereby aiding the reparative forces of the body. The use of heat thus makes the spontaneous response to injury more marked. It also relieves pain in many cases. It must be emphasized, however, that the degree of heat must not be excessive. As ordinarily applied, the effect is quite superficial. Penetration may be increased by diathermy or the infrared ray. The methods of applying heat are described in Chapter 9. Application of cold in acute infections has been recommended by many clinicians and is rather widely used. The authors do not use it. Cold has its definite dangers in the very young, the very old, and over such delicate tissues as the scrotum, eye, and ear.

2. *Operation.* As soon as pus has formed it should be evacuated by incision and drainage, a general principle in the treatment of acute surgical infections. A companion to this rule is the equally important dictum that operations, even simple incisions, should not be done in an area of local cellulitis because

DOCTOR'S ORDERS

Chart 1. Septicemia due to hemolytic streptococcus. Note the septic (spiked) temperature curve. The disease started as an apparently innocent infection of the thumb. The patient, a 10-year-old boy, then developed a deep axillary abscess, later an osteomyelitis of the tibia; he died one month later. At autopsy, abscesses and infected infarcts were found in the liver, kidneys, lungs, and so forth. At the present time, chemotherapy would undoubtedly have prevented the fatal outcome, especially if it were used early in the course of the infection.

the lung or new emboli may detach from areas of septic thrombosis in the lung to establish a pattern of peripheral infarction and visceral abscesses. Osteomyelitis of flat bones is a hazard at all ages, but children also show vulnerability of long bones in the diaphysial region. The kidney, brain, joints, and heart valves are other areas of frequent involvement. Unfortunately, many of these cases are difficult to identify and inaccessible to direct surgical treatment.

GENERAL PRINCIPLES OF TREATMENT

The prevention of infection in traumatic wounds is a major objective of initial surgical management. This is accomplished largely by the accepted technics of fasciotomy to relieve tension, débridement to remove devitalized

indicated. Culture at a later stage will be unreliable because secondary skin invaders soon overgrow the original bacteria.

Rest, elevation, immobilization, and heat are continued. In simple, small abscesses, heat may be omitted. Hot soaks may be used intensively for the first 24 hours. The moist dressing prevents drying and thus aids in promoting drainage as well as mechanically loosening debris and necrotic tissue. Prolonged wet heat, however, is unnecessary and often macerates the tissues.

In the extremities, early active motion is important in order to restore function as quickly as possible. It is begun as soon as subsidence of pain permits it and when evidence of healing occurs. *Evidences of healing* are the diminution of such manifestations as pain, local tenderness, swelling, redness, etc. Wrinkling of the skin is a good indication of the subsidence of the inflammatory swelling.

General Measures. 1. *Skilled nursing care.* This is very essential in the care of patients with septicemia. In addition to general hygienic care and psychologic support, there must be a precise record of temperature, pulse rate, respiratory rate, blood pressure, fluid intake and output, and the general condition of the patient. The fluid intake should be sufficient to maintain a good urine volume (about a liter per day) to provide for the elimination of the increased quantity of metabolic end-products occasioned by the fever and the inflammatory process. Both dehydration and edema are to be avoided.

2. *Antibacterial therapy.* Antibiotics should be given systemically on the basis of determined sensitivity using the bacteria cultured from the patient. The sensitivity tests should be repeated at intervals of three to five days as long as viable bacteria are recoverable. Further details of such treatment are discussed in Chapter 5.

3. *Blood and specific plasma fractions.* These agents are also useful on the basis of specific indications. There is evidence that inflammatory fixation of copper retards hemoglobin synthesis, and there is an associated disappearance of reticulocytes as evidence of diminished erythropoesis. Transfusions of whole blood or of washed and resuspended red cells prevent the progression of anemia. Washed red cells are especially useful for the anemic patient with pulmonary complications that make any blood volume increase undesirable.

Staphylococcemic patients often suffer from hypoprothrombinemia in consequence of the destruction of prothrombin by staphylococci. Both whole fresh plasma and vitamin K preparations are useful in its correction.

Gamma globulin is indicated for those patients shown to have agammaglobulinemia with indolent inflammatory response (8).

More recently, interest has been revived in the naturally occurring bactericidal substances of nonimmune plasma. One of these, "properdin," seems especially promising and is under serious investigative study (9).

4. *Steroid therapy* (10). At the present time, cortisone therapy has become established in the management of tuberculosis meningitis, brucellosis, and typhoid fever. It has also been used for its antiphlogistic effect in the treatment of such nonbacterial inflammations as thyroiditis and pancreatitis. It was realized quite early that cortical steroids were similarly effective in the reduction of fever and the elimination of prostration due to pyogenic coccal infection. In general, however, suppression of the inflammatory response results in enhanced invasiveness for both streptococci and staphylococci and cortisone compounds are contraindicated unless there is adrenal insufficiency or peripheral circulatory failure ("septic shock").

Testosterone is occasionally useful to induce steroid euphoria in a depressed patient or to enhance protein anabolism.

PROGNOSIS

The progress, as regards life, is generally excellent for an adequately treated hemolytic streptococcal infection. In a great number of cases, resolution without surgical intervention is the anticipated result. The major exceptions to this general pattern of recovery are the atherosclerotic extremities of the infected extremity.

Although the great majority of staphylococcal infections are localized and respond well to surgical management, evacuation of pus, either spontaneous or surgical, is a rather regular feature of recovery. Staphylococcemia, however, is still a highly lethal disease and frequently terminates in malignant endo-

Fig. 8. Fatal staphylococcal septicemia following an ill-advised incision of a cellulitis of the upper lip. The illustration shows the condition on admission five days after onset of a small "pimple" and two days after it had been incised. At the present time, the use of penicillin would undoubtedly have cured the infection.

they offer a considerable danger of opening tissue spaces and lymphatic and venous channels to further invasion of virulent organisms.

Though incision and drainage is the operation of choice in the treatment of abscesses, occasionally aspiration alone may be effective. In general, however, a well-placed and sufficiently large incision is needed before rapid and complete healing can occur.

The timing of operation is ordinarily not difficult when suppuration is definite. Too early incision, as just discussed, is apt to be dangerous. Delay in drainage prolongs pain, lengthens the period of healing, and aids in absorption and perhaps of extension of the infection. However, in infections of the face above the upper lip, *operation is practically always avoided* in favor of nature's method of spontaneous drainage, especially because of the danger of spreading the infection to the veins leading to the cranial sinuses (Fig. 8). Moreover, in the face, spontaneous drainage is often prompt and effective. The proper timing for operation may be especially difficult when chemotherapy is used, for reasons previously discussed.

The *incision* is best made with a sharp-pointed bistoury knife in simple, superficial abscesses such as furuncles. The point is inserted into the cavity gently and quickly, with the blade directed upward so that by carrying it outward it enlarges the point of entrance without causing any tension on the inflamed tissue. A single, small slit is often sufficient, but in large abscesses it may be lengthened or a second incision made at right angles to it, the so-called cruciate or crossed incision. The opening, in any case, should be large enough to open the cavity adequately and so located as to favor gravity, or dependent, drainage. When multilocular cavities are present, the barriers may be gently broken down, but it should be realized that strands traversing an abscess cavity are usually blood vessels and vigorous rupture of these strands may result in serious bleeding. Rubber tissue drains produce a foreign body reaction and are usually reserved for the drainage of serous cavities. An adequately exteriorized abscess cavity involving soft parts of the extremities requires only that the skin edges be separated by a light pack of five-mesh (preferably nylon) gauze that may be removed in three to five days.

When the skin over the abscess is already necrotic and insensitive, *anesthesia* is often unnecessary, provided no pressure is made upon it during incision. If the overlying skin is inflamed but still too sensitive, it may be quickly frozen with an ethyl chloride spray just before inserting the bistoury knife. If the skin over the abscess is uninvolved by the infection, it may be anesthetized with Novocain. In certain sensitive patients a short gas inhalation may be advisable. General anesthesia is particularly indicated in most infections of the hand and in any large abscess when exploration of the cavity will be necessary. Usually nitrous oxide is sufficient.

The evacuated pus should be smeared and cultured as a routine. Unsuspected organisms, the identification of which may prevent diagnostic and therapeutic errors, may thus be detected. Sensitivity tests against antibiotic agents should be carried out in all serious infections to allow more effective therapy when

Rarer Types of Miscellaneous Surgical Infections

There are numerous miscellaneous surgical infections which cannot be classified readily as regional diseases. They are assembled and discussed in this chapter as miscellaneous infections. The causative agents are extremely varied, including bacteria of various types, viruses, yeastlike organisms, parasites, and agents still undiscovered. Some are very serious, responding poorly to treatment, whereas others respond well to modern chemotherapy. Some of these diseases are not primarily surgical but are caused by injury or animal bites and simulate surgical lesions. Accordingly they are of definite surgical significance not only from the diagnostic standpoint but because some require operative therapy.

TETANUS

The etiologic factor in this disease is *Clostridium tetani*, an anaerobic, spore-forming, gram-negative bacillus which was first described by Nicolaier in 1884. The spores are extremely resistant to drying and will survive boiling for one hour in plain water. It is regularly found in the intestinal tract of the horse, less frequently in many other domestic animals, and to a considerably less extent (20 to 30 per cent) in the intestinal tracts of human beings. The bacillus is likewise widely distributed in soil which has been fertilized with manure.

Since the organism is anaerobic, the disease is more apt to follow deep and punctured wounds in which necrotic tissue and pyogenic organisms are present. The consumption of the oxygen in the tissue of the wound by the pyogenic bacteria creates the anaerobic conditions necessary for the growth of the tetanus organism and thus the production of the disease.

Important in the pathogenesis of tetanus is the fact that, whereas tetanus organisms are harmless if injected in pure culture into the normal tissue of susceptible animals, they multiply and produce toxin if the tissues are damaged by mechanical means or by infection with other bacteria. Although the bacilli have been cultured from lymph nodes adjacent to infected wounds, they tend to remain locally in the wound. In the United States tetanus is more common in the South than in the North, being particularly prevalent in the states bordering the Gulf of Mexico. Confusion still exists as to the mechanism through which the toxin exerts its fatal effect. However, since the work of Abel (1936), it is agreed that the old theory of passage of toxin to the spinal cord by way of the axis cylinders of the peripheral nerves is erroneous. Abel found that tetanus toxin is fixed by the tissues; only when more than a lethal dose was given could any be recovered from the circulating blood and lymph. Moreover, Firor and asso-

carditis (11). It is for this reason that all staphylococcal infections should be given meticulous care during their initial and pre-invasive stages of development.

symptoms of tetanus. Should this area again be injured, as, for example, by a secondary operation for removal of a foreign body, the patient may then contract the disease. *For this reason, another prophylactic dose of antitoxin must be given at the time such secondary operations are performed, if more than ten days have elapsed since the initial prophylactic dose of antitoxin.* Fortunately, however, if tetanus develops even after the passive immunity produced by the initial prophylactic injection wears off, the disease will be mild. The danger of development of sensitivity to horse serum by subsequent doses of antitoxin is one of the many reasons for starting active immunity with toxid (see below) when the antitoxin is used at the time of injury.

The injection of toxoid,* as popularized by Ramon and associates (2), makes it now possible to produce an active immunity to tetanus lasting four or five years and perhaps permanently. For example, Stafford and associates (3) have found measurable levels of tetanus antitoxin in human serum at least 11 years after active immunization. Active rather than passive immunity is especially valuable in military surgery or for those in whom injuries are extremely frequent because it obviates the need for a second dose of antitoxin which is so apt to result in a serious allergic or anaphylactic reaction. Very little immunity is conferred by the first dose of toxoid. However, when a second dose is given two to four weeks later, definite immunity is conferred within four to six days. A third dose produces a marked rise in antitoxin titer which is maintained for years.

Two injections (1 ml. each) of toxoid are given at intervals of 4 to 6 weeks and a third 6 to 12 months later; a booster dose should be given every 4 to 6 years and at the time of subsequent injury. This method is very effective in prophylaxis and is used for all military personnel. Experiments in mice conducted by Taylor and Novak (4) indicate that penicillin may also be very effective in the prophylaxis of tetanus, but the results were still better when antitoxin was also given. The experiments are of sufficient significance to justify huge doses of penicillin in the treatment of tetanus in human beings.

The question has been raised as to whether active immunization should be started together with antitoxin because of the possibility that antitoxin may interfere with the production of toxoid immunity (5). However, in individuals not previously immunized with toxoid but given antitoxin for treatment of a wound, some authorities (6) recommend that toxoid should be given at the same time but with a separate syringe at a different site. If a patient previously immunized with toxoid sustains an open wound, antitoxin may nevertheless be indicated if 1. the wound is massively contaminated; 2. treatment including the booster dose is delayed more than two or three days; and 3. more than four or five years have elapsed since active immunization.

The great danger in administration of antitoxin is the development of *anaphylactic shock* (manifestations of which include marked tachycardia, laryngeal stridor, bronchial spasm, cyanosis, and collapse), which, if severe, may result fatally within a very few minutes after the injection. Death occurs only in patients extremely sensitive to horse serum and is rare indeed, except as an immediate reaction.

Before tetanus antitoxin is administered, inquiry should be made as to whether the patient has had any injections of serum within the past several years or is subject to asthma, hay fever, or urticaria. If there is any possibility that the patient is sensitive to horse serum, it is preferable to inject a small drop of antitoxin (0.1 ml. of a 1:10 dilution in saline) intradermally with a fine needle. If the patient is sensitive to horse serum, a large wheal surrounded by a hyperemic zone will develop within a few minutes. Under these circumstances, bovine antitoxin may be tried. If the patient is sensitive to that also, desensitization to one (horse serum) should be carried out. This can be accomplished fairly adequately by the frequent injection of graduated doses of serum. The method recommended by Spaeth (7) is as follows: "Inject 0.1 cc. of a 1:100 dilution of antitoxin subcutaneously. Subsequent doses are given at 15 minute intervals. The second to fifth injections are 0.1, 0.2, 0.4, and 0.8 cc. of a

* Toxoid is made by addition of formalin, agar, alum, and other substances to tetanus toxin. The alum-precipitated toxoid appears to be most satisfactory.

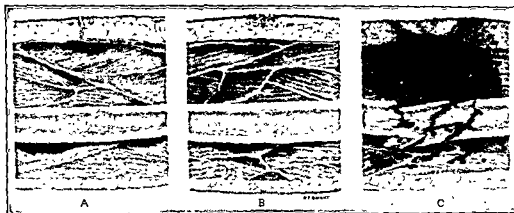

Fig. 1. Types of wounds which are particularly prone to result in tetanus unless adequate prophylactic therapy is instituted (see text). A, punctured wound inflicted by a dirty nail; the anaerobic conditions resulting from this type of wound, along with the foreign bodies (rust, dirt, and so forth), are conducive to the growth of tetanus bacilli. B, wound inflicted by blank cartridge pistol. Note the tiny but numerous perforations of the skin, and the implantation of such foreign bodies as burned powder, paper wadding, and particles of clothing in the subcutaneous tissues. C, wound inflicted by shotgun at close range. Note the enormous destruction of tissue, including bone, and the large number of foreign bodies (shot). This type of wound is also very prone to result in the development of gas gangrene.

ciates (1) found that the toxin does not travel up the spinal cord to the brain; they suggested also that "the toxin in the spinal cord is altered into or liberates a different lethal agent which is transported to and has its lethal effect on vital centers." Their experiments showed that this lethal agent was not neutralized by antitoxin.

Prophylaxis and Immunity. Theoretically every patient sustaining a contaminated wound extending through the skin should have the benefit of prophylactic treatment which may be one of three types: antitoxin, booster dose of toxoid, or procaine penicillin G. However, if careful judgment is exercised, a large percentage of patients with minor lacerations need not be given prophylactic treatment. For example, a superficial laceration sustained by a housewife while washing glassware or dishes which are used and cleaned daily is not apt to be contaminated with tetanus bacilli. Wounds sustained in the street and punctured wounds produced by rusty nails or sharp objects lying in contact with filth or soil are apt to be contaminated with tetanus bacilli. In such instances an injection of 1,500 units of tetanus antitoxin should be given. This dose may be reduced slightly in children, but it *cannot safely be reduced in direct proportion to the weight*. Some advise giving much larger prophylactic doses (Spaeth). It must be emphasized that tetanus antitoxin acts only in neutralizing toxin; it has no effect on the growth of the bacilli. Débridement of the wound (except infected and punctured wounds), removing blood clots and foreign material and excising dead tissue (see Chapter 14), is also important in prevention of tetanus. When the wound is extensive (Fig. 1c) and contamination with tetanus bacilli seems obvious (e.g., gunshot wounds or injuries sustained in barnyards), the prophylactic dose should be increased to 5,000 units. If the patient is seen 24 hours after injury, the initial dosage of 1,500 units should be doubled; it should be doubled for each additional day of delay up to a total dose of 10,000 or 12,000 units. Since the *passive immunity conferred by the administration of antitoxin lasts only 10 to 14 days*, it may also be advisable to repeat the injection in about 10 days, especially if the wound was extensive and tissue destruction so great as to prevent rapid healing. If the wound heals slowly because of infection or other causes, the dose of 1,500 units should be repeated every seven or eight days. Usually, however, the wound has healed so completely by the time the passive immunity has worn off that the local immunity of the tissue surrounding any remaining tetanus bacilli is sufficient to prevent the growth of the organism. It is a well-known fact that tetanus spores may survive in tissues for months without producing

Fig. 2. Opisthotonos in third day of tetanus; death six hours later in convulsions. (From Ashurst. Surgery, Lea & Febiger.)

eign bodies; no attempt should be made to close the wound. If the wound is massive, it should be filled with a creamy suspension of "effective" zinc peroxide and then covered with petrolatum gauze to prevent evaporation. Large doses of penicillin (up to 1,000,000 units per day) should be given on the assumption that the bacilli may still be multiplying in the wound area even though the wound has been excised. Penicillin has no effect on toxin absorption or neutralization. Most authorities advise excision of a healed wound, assuming it is the source of the infection.

The patient must be kept in a quiet and dark room. Every possible effort should be exerted to *control the convulsions with heavy doses of narcotics and sedatives.* Gnagi (8) was among the first to recommend large doses of sedatives (first using sodium amytal) in controlling the convulsions. The rectal administration of avertin has been used a great deal, but its known toxicity on the liver and its tendency to produce hypotension preclude

Fig 3. Risus sardonicus as observed in a patient with tetanus. (Drawn from DeQuervain.)

1:10 dilution subcutaneously. The remaining injections consist of progressively doubled doses of undiluted serum by the intramuscular route, beginning with 0.1 cc." In the presence of active disease, desensitization is conducted more rapidly by giving larger and fewer doses, particularly if convulsions are present. Adrenalin should be given to combat any reaction sustained. Cortisone is also of value.

The term *serum sickness* has been assigned to the late allergic response of the body to the foreign serum and is fortunately encountered in only a small percentage of patients given tetanus antitoxin. This sensitivity may be due to a previous injection of serum or may be an inherited characteristic. In the latter instance, reactions are more apt to be anaphylactic in character. Symptoms appear 4 to 10 days after the injection and are usually ushered in by a generalized itching, urticaria, or erythematous rash of the skin, appearing first at the site of injection. Fever is not uncommon, especially in children; stiffness and pain about the joints is frequently complained of. Generalized enlargement of lymph nodes is common. Such nodes are usually tender to palpation but, of course, do not suppurate. If symptoms are severe, cortisone, ACTH, adrenalin, or one of the antihistaminics like benadryl should be tried.

Clinical Manifestations. The incubation period of tetanus varies from 4 to 10 days but may be delayed several weeks by such mechanisms as insufficient prophylactic antitoxin. In the acute cases death usually occurs within four to five days. The longer a patient lives after the onset of symptoms, the better are his chances of recovery. It is likewise true that the severity of the disease decreases as the length of incubation time increases. On the other hand, the disease is much more serious when the wound is near the brain (i.e., head and neck).

Usually the first symptom noted is limitation of movements of the jaw due to muscle spasm (lockjaw or trismus) although pain in the jaw often occurs early. It should be remembered, however, that lockjaw is most commonly produced by inflammatory lesions about the jaw. Stiffness of the neck and cramps or stiffness of the muscles in the region of the wound soon follow. The muscles of deglutition are also affected, sometimes to the extent that it is impossible for the patient to swallow. Laryngeal spasm may be of sufficient severity to produce respiratory difficulty. Hesitancy in micturition caused by spasm of the sphincter is common. In the more acute cases, spasm of the muscles of the back may be so marked as to produce opisthotonos (Fig. 2). The eyes are usually fixed and staring. Spasm of the facial muscles (Fig. 3) produces the sardonic smile (risus sardonicus) which is notoriously known to accompany the disease. The rigidity of the muscles of the jaw may be so great as to prevent mastication and require liquid feeding, often by means of a nasal catheter. If the catheter provokes laryngeal spasm, it may be necessary to resort to intravenous feeding.

In addition to the tonic spasms described above, clonic spasms or convulsions develop later in the disease. The peripheral irritation producing these convulsions need be nothing more than a slight sound or light touch. The hideous facial expression of the patient in a convulsion is so impressive as not to be forgotten. The temperature may be normal or elevated, except that there is always a terminal hyperpyrexia. Sweating is profuse, particularly in the acute cases. Tachycardia is not pronounced except shortly before death.

Treatment. The treatment of tetanus is curative only when instituted early and in mild cases. As soon as the diagnosis is made, tetanus antitoxin should be administered in large quantities, assuming of course that proper attention is given to the possibility of sensitivity to horse serum as discussed under Prophylaxis and Immunity. Recent investigations suggest that the intravenous method of administration is superior to others. The dose on the day of admission should obviously be larger than on the succeeding days. As a routine, 100,000 to 200,000 units should be given the first day. Additional serum should be given daily in smaller doses as indicated by progress of the disease. Many authorities advise giving 10,000 to 20,000 units of antitoxin intrathecally, although there is really no clinical evidence that this method of administration improves the results.

There is not complete agreement as to the treatment of the wound, but the authors advise early débridement and removal of for-

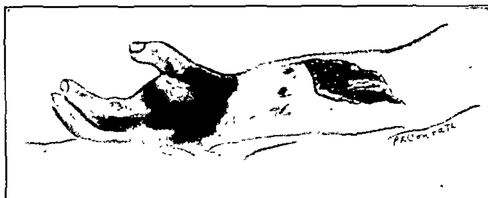

Fig. 4. Gas gangrene in a patient following a compound fracture of the forearm. When admitted to the hospital 30 hours after injury there already were marked swelling of the forearm with crepitation, patches of gangrenous skin, and the typical offensive odor. Amputation was performed in the upper third of the arm several inches above the limits of crepitation. Within 24 hours the crepitation had involved the stump and shoulder. Patient was given massive doses of perfringens (anti-gas gangrene) antitoxin and made a miraculous recovery; sulfonamides and penicillin were not yet available.

10 to 12 hours after injury. The crepitation produced by the forceful diffusion of air into the tissue by trauma may frequently resemble a gas gangrene in its incipiency, but observation over a period of a few hours relative to the progression of the crepitation should quickly differentiate between the two conditions. A profuse, clear or slightly turbid, brownish exudate drains from the wound and is associated with an offensive odor of putrefying flesh, which is so specific as to be almost pathognomonic of the disease. Gas bubbles may be seen in the discharge. Yellowish, bronze-colored, or ecchymotic areas, which rapidly become cyanotic and then gangrenous (Fig. 4), may appear in irregular patches in the skin surrounding the wound due to impaired blood supply. From the onset, the patient appears very ill, presenting many of the symptoms of shock. Delirium is frequently encountered. Pain is variable but usually prominent. The causative organism may be found in the discharge from the wound a few hours after the accident and, usually, before symptoms appear. Occasionally, however, gas-producing, anaerobic bacilli can be found in the wounds (anaerobic cellulitis) of patients who do not develop gas gangrene. Presumably, tissue immunity or efficient treatment has prevented the inception of the disease in such cases.

A roentgenogram of the affected extremity may reveal, in the soft tissues, collections of gas which cannot be demonstrated by palpation. In spite of the brilliant work of Weinberg in isolating various strains of anaerobic organisms capable of producing the disease, it appears that the bacteriology of the disease is still unsettled. For example, the amount of gas produced by the various strains of organisms is extremely variable, and, on many occasions, the disease may be present even in a severe form with the production of only a small amount of gas.

Treatment. Early and thorough débridement (particularly with excision of devitalized muscle) minimizes development of the disease. Badly contaminated wounds in which gas gangrene is apt to develop should be left open after débridement and packed gently with gauze.

Once the disease has developed, active treatment must be begun immediately.

1. *Operation, consisting of exposure of the* involved areas and excision of devitalized tissue, particularly muscle, is perhaps the most important single procedure of value. In advanced cases where toxicity is severe and life seriously jeopardized, immediate amputation of the guillotine type may be indicated; this is rare, however, if proper excision and incision of tissue is carried out.

2. Penicillin in large doses (300,000 to 500,000 units the first day) should be given intravenously and intramuscularly.

3. The wound should be packed gently with a creamy suspension of "effective" zinc peroxide and gauze; the wound is then cov-

its continued use. Sodium evipal and sodium pentothal are satisfactory, particularly for intravenous use in stopping convulsions. Curare may likewise be useful in reducing muscular rigidity if extreme caution is taken regarding dosage. Prevention of convulsions is extremely important because the symptoms produced by the toxin are apparently more responsible for the patient's death than the toxin itself; all clinicians now agree on this point. If muscle spasm prevents swallowing, feeding by nasal tube may be necessary. Usually intravenous feedings are indicated. If laryngospasm is present, tracheotomy will be indicated to aid in the expulsion of pulmonary exudate and to permit easier tracheal aspiration, thus making respiration easier. Cortisone or hydrocortisone may be helpful (9), but these drugs are by no means curative. Good nursing care is very important. As stated, the *prognosis* of the fulminating case is poor. However, if the adequately treated patient survives the first 48 to 72 hours, recovery may be expected. In general, the mortality rate is lower if the disease develops despite a prophylactic dose of antitoxin.

GAS GANGRENE

The causative organism was at first thought to be specifically *Clostridium perfringens (welchii)*, originally designated as *Bacillus aerogenes capsulatus*. It has been demonstrated, however, that there are many other anaerobic organisms capable of producing gas gangrene; in order of frequency they are *Cl. novyi* (*B. oedematiens*), *Cl. septicum* (*Vibrion septique*), and *Cl. histolyticum. Cl. bifermentans* (*Cl. sordelli*) and *Cl. sporogenes* are of less pathogenic significance, the latter organism being proteolytic but producing no toxin. In many instances, colon bacilli and aerobic cocci, particularly the streptococci, prepare the tissues for the development of the disease. Gas gangrene rarely occurs except in massive, dirt-contaminated wounds in which there has been considerable destruction of tissue, especially muscle. A true gas gangrene infection primarily attacks the muscle, which early becomes cyanotic and edematous (*necrotic myositis*). It fails to bleed upon cut section, presumably because of vascular thrombosis or compression due to edema. Invasion may also take place between muscular sheaths or along fascial planes. Compound fractures seem to encourage the development of the disease. Gas gangrene may occasionally be encountered in wounds in which none of the so-called gas bacillus group of organisms is present. In such cases (*anaerobic cellulitis*), very little gas may be noted in the tissues, but discoloration, edema, and destructive features are nevertheless present; the mortality rate is not as high as in the typical gas gangrene.

Clostridial infection really occurs in two forms—a cellulitis and a myositis. The distinction between the two is extremely important, for, while the former is much more common than the latter, it is the infection of the muscle which is the more serious disease and leads to the high mortality. It is probable that much confusion and difference of opinion in regard to treatment in clostridial infections is based upon failure to identify the site of infection. When the superficial tissues are involved, i.e., clostridial cellulitis, treatment may be relatively simple and a favorable outcome expected. However, when the muscle is involved, i.e., clostridial myositis, radical treatment is necessary, and the outcome is frequently fatal. Clinically, cellulitis is distinguished from myositis by the absence of profound toxemia and by relatively moderate pain, whereas in clostridial myositis the onset is sudden, with pain approaching the clinical appearance of shock. The detection of gas in the wound is less important since it may be present with other types of anaerobic infection. Positive differentiation can be made at operation by observing the muscle and the extent of the wound.

Clinical Manifestations. Symptoms are apt to occur 10 to 12 hours after the injury. Fever, tachycardia of an unusual degree, prostration, and restlessness develop early and frequently progress in such a rapid fulminating manner as to cause death in two or three days. A feeling of tension in the wound or of tightness of the dressing is an early and fairly constant symptom; it therefore should never be ignored when complained of by the patient. Swelling about the wound may occur so rapidly as to resemble a progressive hematoma. Crepitation produced by gas in the soft tissues, likewise, may be elicited as early as

Fig. 6. Sulfur granule of actinomyces. Colony of actinomycosis with well-developed clubs at the periphery in a nodule in the peritoneal cavity of a guinea pig inoculated with a culture from another guinea pig. Paraffin section. Low magnification. (From Jordan. General Bacteriology, W. B. Saunders.)

and desquamation appears. Suppuration is uncommon.

Treatment. Despite the low degree of contagion, the patient should be isolated. The mortality rate in the aged and in infancy was extremely high before the institution of chemotherapy. Penicillin is the agent of choice and should be given in a dosage of 600,000 to 800,000 units the first day but may be reduced for the remaining few days during which active treatment will be indicated. With few exceptions, the disease is completely controlled with penicillin in 24 hours.

Erysipeloid is an infection of the skin which resembles erysipelas in appearance only. Often called "fish poisoning," it is acquired from handling fish and is really an occupational disease.

ACTINOMYCOSIS

The etiologic factor in actinomycosis is the actinomyces or "ray" fungus, the most important bacteriologic feature of which is the sulfur granule (Fig. 6) which is just large enough to be recognized by the naked eye and consists of microscopic filaments, coccuslike bodies, and clubs. Finding sulfur bodies in the pus from a lesion establishes the diagnosis, but it should be emphasized that they may be difficult or impossible to demonstrate, especially in sinuses of long duration; in a fresh abscess, however, they are numerous. There are numerous strains of the organism, most of which, as observed in man, are not the same strain that produces lumpy jaw in cattle. Some of the strains grow better culturally under aerobic conditions, whereas others grow better anaerobically. The portal of entry is usually the mouth; the organisms may penetrate the mucous membrane into the neck, enter the lungs by way of the trachea, or be swallowed and attack the cecum and appendix. Actinomycetes which are often found in the mouths of healthy individuals may be the source of the infection. Actinomycosis is a granulomatous disease which tends to invade with destructive characteristics but *does not attack the lymph nodes.* There is scarcely any tissue other than the lymphatic system that is immune to invasion. This no doubt adds to the difficulty in establishing a clinical diagnosis. Bone is readily attacked, and, in one patient observed by the authors, the organism had perforated the base of the skull with the subsequent development of a meningitis. The incubation period is not clearly established but undoubtedly varies within very wide limits.

Clinical Manifestations. The neck is perhaps the most common site affected. The disease is encountered in the abdominal cavity, primarily in the cecum and appendix. It is less commonly observed in the lungs and pleural cavity.

1. In the *head* and *neck,* the infection usually begins as a hard, superficial nodule which finally softens, breaks down, discharges pus and sulfur granules, and ultimately forms a sinus tract (Fig. 7). Before this, however, a boardlike induration surrounding the initial lesion usually develops; the lymph nodes are not involved. Tenderness or pain is not significant but may be pronounced when bone is involved. The sinuses may burrow deeply and form small abscesses or collections of pus, some of which may be secondarily infected if an external sinus is already present. The pus characteristically is thin and heterogeneous

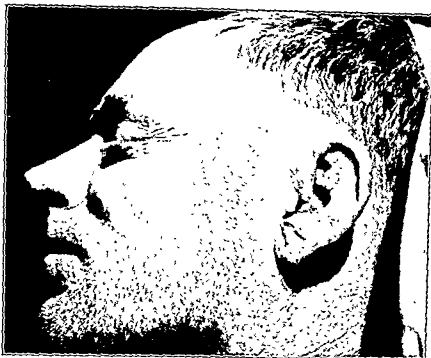

Fig. 5. Erysipelas of the face and ear. Photograph taken 24 hours after onset, which developed with a chill and fever. Note the edema. The raised precipitous edge which is characteristic of erysipelas is present to a moderate degree in this patient. (St. Louis City Hospital.)

ered with petrolatum gauze to prevent evaporation. This dressing must be changed daily.

4. Although there is little evidence that gas gangrene antitoxin is effective, it may be given, providing proper precautions are taken regarding sensitivity as described on pages 103 and 104.

5. Kelly has reported radiotherapy to be effective, but others have not obtained the same favorable response.

The mortality rate should be much below the 50 per cent reported during and after World War I. Langley and Winkelstein (10) reported that the mortality rate among military casualties was only 11.5 per cent in 96 cases in which they utilized surgery, antitoxin, and, particularly, penicillin.

ERYSIPELAS

Erysipelas, which was commonly known years ago as St. Anthony's fire, is an acute inflammation of the skin (Fig. 5), especially of its capillary lymphatics, and is caused by *Streptococcus erysipelatis*. At present, it is fairly rare and not very serious because it is so effectively amenable to chemotherapy. Usually there is no visible lesion to explain the entrance of the organism into the skin. Presumably the invasion is made through tiny fissures or lesions microscopic in size. The contagious element to the disease has been exaggerated. Cooke (11) is of the opinion that the disease is contracted by autoinoculation, that is, without coming in contact with an active case of erysipelas. The fact that the incidence of the disease shows equal distribution in males and females during infancy and childhood but changes to 60 and 40 per cent respectively after the age of puberty, when shaving is prevalent, appears to support the theory of autoinoculation.

The skin of the face is by far the site most commonly affected, but the skin of any portion of the body may be attacked. A red, edematous, tender, and slightly raised area appears quite suddenly and usually shows a tendency to spread rapidly but in no specific direction. Almost simultaneously with the appearance of the initial lesion, the patient develops fever and frequently chills. Fever, however, may on rare occasions be absent. Pain and tenderness are extremely variable and may be absent. The border of the lesion is sharply defined and presents the most conspicuous evidence of inflammation. The reaction at the point of origin gradually fades,

Fig. 9. Multiple sinuses of the back due to actinomycosis, in a girl 16 years of age. Onset two years previously with pain in chest, followed two weeks later by the development of a sinus under the right breast. Since that time, numerous other sinuses appeared, particularly over the back. X-ray revealed a destructive process involving the first and second lumbar vertebrae and a thickening of lung markings; each process resembled tuberculosis but was undoubtedly due to actinomycosis. Sulfur granules were found in a fresh abscess on the back but were absent in the discharge from the chronic sinuses.

able there is no way of determining whether or not the actinomycetes were instrumental in the development of appendicitis in such instances; however, it appears that the disease is often primary in the appendix and spreads to the cecum from that point. Usually, the onset is insidious with mild pain in the right lower quadrant associated with the development of a mass in the cecal region. Sinuses may form anywhere about the abdomen and are frequently observed about the pelvis and back (Fig. 9). The liver may become involved but usually only as a manifestation of a generalized infection; subphrenic abscesses are occasionally encountered arising from lesions in the liver or cecum.

3. *Thoracic* actinomycosis usually follows invasion of an active initial lesion in the neck or abdomen. Aspiration of the organisms into the respiratory passages may also be responsible for the disease. The symptoms may simulate those of pulmonary suppuration (particularly tuberculosis), including cough, pain on respiration, fever, expectoration, sweating, and loss of weight. As the disease progresses, the pleura and finally the thoracic wall, including the ribs, are involved with the subsequent development of sinuses leading to the exterior.

Treatment. Contrary to general belief, a cure may be expected if the diagnosis is made early. Perhaps the most important of the various therapeutic measures is surgical, i.e., adequate drainage of abscesses, excision of necrotic tissue, and free drainage of the wound (Wangensteen). Penicillin is quite effective, but it must be given in huge doses (as much as 1,000,000 units per day) and continued over a long period. Sulfadiazine, in a dose of about 4 gm. per day for an adult, should be given simultaneously. On certain occasions, x-ray therapy is helpful. It is to be emphasized, however, that, when the disease is disseminated so that major organs, such as the liver and bones, are involved, the chance of obtaining a cure is greatly diminished, regardless of the type of therapy used.

VENEREAL LYMPHOGRANULOMA

This disease is known by several names, including lymphogranuloma inguinale, esthiomene, tropical bubo, and lymphopathia venereum. The French investigators (Durand, Nicolas, and Favre), who described it in 1913 as a definite entity, recognized it as being of venereal origin and as being caused presumably by a virus which entered the body through a tiny unnoticed primary lesion on the genitals. The incubation time varies between five days and three weeks. The Negro race is affected much more commonly than the white. Manifestations are encountered much more commonly in females than in males.

Before the advent of penicillin and other agents so effective in the treatment of syphilis, Gray and associates (12) found the disease slightly more prevalent in the Negro race than was syphilis. They noted that, in a series of nearly 500 Negro hospital patients, 40 per

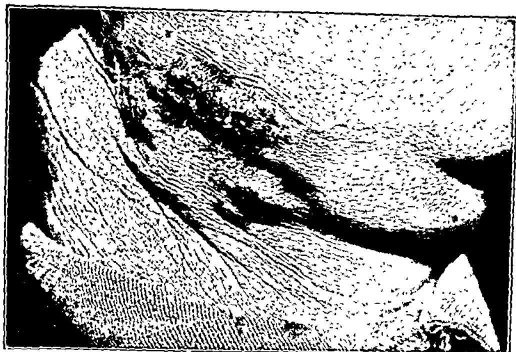

Fig. 7. Actinomycosis of jaw. (From Wohl. M.A. J.A.M.A.)

and contains flaky necrotic material. Sulfur granules are rarely demonstrable except in fresh abscesses. Fever may or may not be present.

2. The *abdominal* type presumably is caused by implantation of swallowed organisms upon a small lesion or ulcer in the mucosa of the intestine, usually the cecum or appendix (Fig. 8). The first symptoms of cecal actinomycosis may be acute and *may simulate appendicitis.* Thus, many cases of actinomycosis of the cecum develop after the patient has been operated on for acute perforated appendicitis. With the evidence avail-

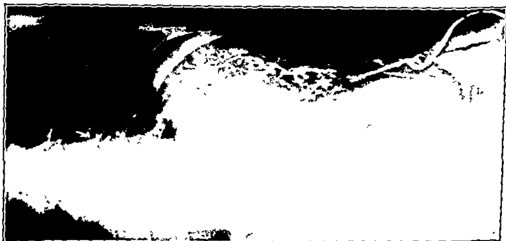

Fig. 8. Abdominal and thoracic actinomycosis. The patient, a 65-year-old housewife, first developed acute abdominal manifestations, was operated upon, and a perforated appendix removed. A mass appeared in the right lower quadrant three months later, which was incised; pus was encountered in which the ray fungus was found. Later, abscesses formed in the lumbar region and thoracic cavity from which the actinomyces were identified and cultured. The x-ray photograph was taken after Lipiodol had been injected into the sinus in the abdominal wall leading to the abscess; note the outline of the bronchi and the shadow indicating the subphrenic and pleural abscess. This patient was observed before the advent of chemotherapy. Treatment consisted of intensive radiotherapy, sodium iodide, and incision and drainage of abscesses. All incisions remained healed for 15 years, during which time the patient was observed.

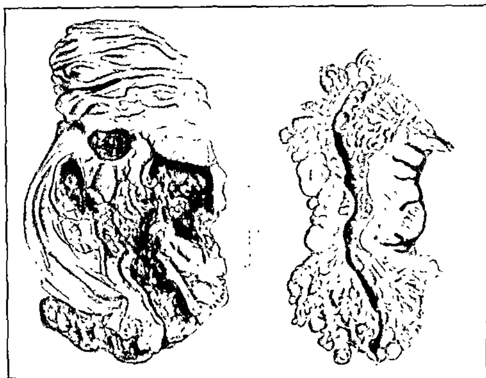

Fig. 11. Longitudinal section of stricture of rectum due to venereal lymphogranuloma. Each illustration represents specimen removed at operation. Note that the stricture extends not more than 6 to 8 cm. above the sphincter. Areas of ulceration are found scattered over the scarred mucosa. (Drawn from Gatellier and Weiss.)

prominent and the nodes may suppurate. If the suppurating nodes are not incised, they readily break through the skin spontaneously and form sinuses. Suppuration and sinus formation may last for variable lengths of time. In some instances, healing has taken place in as short a time as three weeks. On other occasions, the nodes have been known to exist for as long as two years.

In the female, ulcerating proctitis with mild tenesmus and passage of blood, mucus, and pus in the stool is usually the first significant symptom. This may persist for two or three years or longer. At least three-fourths, and perhaps all, of the benign strictures of the rectum are caused by venereal lymphogranuloma (Fig. 11) and are a sequel (two to three years later) to ulcerative proctitis. Benign stricture of the rectum will produce symptoms referable to the narrowing of the lumen —namely, tenesmus and diarrhea with liquid or pencil stools. These benign strictures of the rectum persist indefinitely, but the patients frequently adjust themselves so that they have frequent liquid stools and suffer very little inconvenience from the stricture. Occasionally condylomatous lesions about the anus are observed (Fig. 12). Elephantiasis of the genitals (particularly the vulva and penis) is not uncommon. Fistulas about the rectum are common.

Diagnosis. The Frei test is remarkably valuable and accurate, since positive tests have been obtained as long as 12 to 15 years after the onset of the disease. The antigen is injected intradermally in the quantity of 0.1 ml. A typical positive reaction appears in the skin surrounding the induration.

When the disease primarily affects the lymph nodes, it is often confused with lymphadenitis caused by a chancroid. The gradual enlargement of the lymph nodes, associated with a variable amount of pain, followed ultimately by suppuration, are identical in the two diseases. However, an important difference is the size of the initial lesion, which, in lymphogranuloma, is small (seldom larger than 0.25 cm. in diameter), and, in a chancroid, is large (1 to 2 cm. in diameter). The initial lesion in a chancroid is apt to be mul-

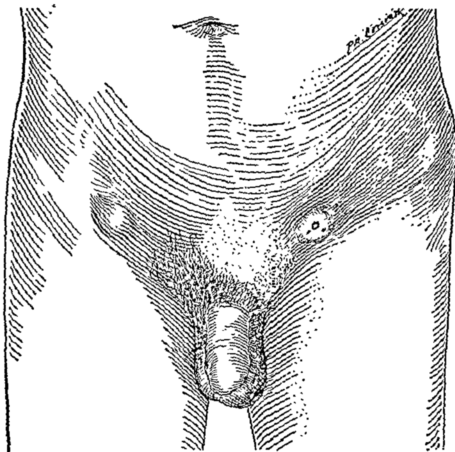

Fig. 10. Bilateral lymphogranuloma inguinale. The nodes on the patient's left have suppurated, resulting in the formation of a sinus as noted. The nodes on the right are enlarged but did not suppurate, although about five months were required for subsidence of the process on each side.

cent of the males and 40 per cent of the females had positive Frei tests. In a smaller series of white patients, they obtained positive Frei tests in only 3.4 per cent, again with an equal incidence in males and females. Only a small portion of the patients with positive Frei tests had symptoms of the disease. Since this test is known to be highly specific, it may be assumed that the vast majority of patients with positive Frei tests had recovered from the disease without clinical manifestations. The pathogenesis, along with other data on the transmission of the disease described by various authorities, has been discussed in detail in the monograph by Stannus (13). The disease is readily produced in various types of animals by local inoculation, particularly into the brain.

Clinical Manifestations. The disease manifests itself in one of three ways. In men the most common feature is 1. involvement of the inguinal lymph nodes which frequently goes on to suppuration. In women the most common complaint is referable to 2. an ulcerative proctitis which, at least in Negroes, frequently results in 3. stricture of the rectum. Occasionally inguinal lymphadenitis and ulcerative proctitis exist simultaneously.

The onset of the disease is frequently characterized by diffuse severe abdominal pain of a cramping nature. Fever, nausea, and, rarely, vomiting may accompany the abdominal pain. Loss of weight is commonly observed and multiple arthritis is not uncommon. Severe systemic manifestations, however, are usually associated with extensive infection and fistulas around the rectum and perineum; they occur almost always in the female and often two or three years following the onset of the disease.

In the male, the lymph nodes of one or both sides enlarge insidiously without the production of much pain (Fig. 10). After a few weeks the pain and disability become more

Fig. 13. Chancre of the penis.

frequent dilatations, but, in severe cases, especially those with superimposed infection and multiple fistulas, colostomy may be indicated.

SYPHILIS

Syphilis is caused by *Treponema pallidum* (*Spirochaeta pallida*) and is acquired primarily by sexual contact. Because penicillin is so effective in therapy, this disease has become much less frequent during the past 10 years. Syphilis may affect any organ of the body and in such a variety of ways that the disease is of surgical significance, especially from the standpoint of diagnosis. Numerous serologic tests, including the Kahn, Wassermann, Kline, Kolmer, and Hinton, are in use and are extremely valuable in establishing the diagnosis.

The *primary* stage, or chancre, appears usually on the genitals (Fig. 13) and sometimes on the lip, three to four weeks following exposure. The lesion is flat, indurated, buttonlike, and ulcerates after several days. From this ulceration, the spirochete is readily isolated and identified with the aid of dark field examination. The lesion is indolent and does not heal for several weeks without active treatment. Regional lymph nodes may enlarge painlessly but never break down unless secondarily infected with pyogenic organisms. Six to ten weeks after the primary lesion appears, the *secondary stage*, which is an expression of the systemic invasion by the spirochetes, appears. The accompanying eruption over the skin and mucous membranes (mucous patches or leukoplakia) has varied characteristics. At varying intervals, from a few months to several years, the *tertiary stage* develops. The gumma which typifies this stage is of variable size and may appear in any tissue or system of the body. Gummas are smooth and soft, and, because of associated arterial lesions such as thrombosis and endarteritis, are avascular and may break down, forming a necrotic mass. (Fig. 14). True suppuration, however, does not occur without secondary pyogenic infection. Cutaneous tertiary lesions or syphilides may appear and produce stubborn ulcerations, which are commonly seen on the leg.

Mouth. Hutchinsonian teeth and scarring about the mouth are manifestations of congenital syphilis. Primary lesions may occur on the lips or tongue and be occasionally mistaken for carcinoma, but gummas of the tongue are of much greater surgical significance because of the enormous amount of destruction of tissue in some cases and because of the frequent association with carcinoma. The differentiation between gumma and carcinoma of the tongue frequently cannot be made without a biopsy. Occasionally syphilitic leukoplakia simulates that associated with squamous cell carcinoma (see page 385).

Nose and Throat. Although redness and edema of the pharynx are rather constant accompaniments of early syphilis, the rarer lesions (gummas) are much more significant surgically. Gummas of the nasal septum may

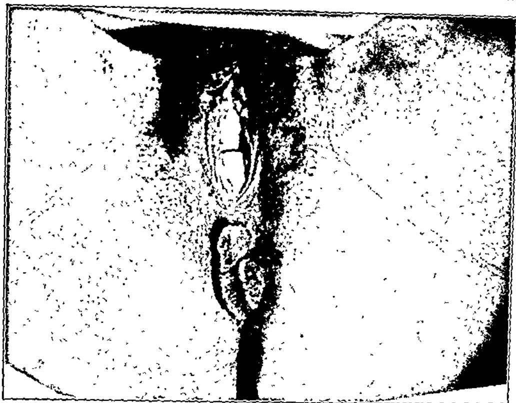

Fig. 12. Condylomas due to venereal lymphogranuloma. Such lesions develop insidiously and may or may not be associated with ulceration. This patient had a rectal stricture; the Kahn test was negative. Previous to identification of the disease in 1913, almost all lesions of this type, as well as strictures of the rectum, were considered to be of syphilitic origin; most of them are due to venereal lymphogranuloma.

tiple; in lymphogranuloma it is usually single and even unnoticed in males but is frequently multiple in women. Sensitivity tests will usually differentiate—the Frei test is specific for venereal lymphogranuloma and the Dmelcos test for chancroid.

When limited to the inguinal lymph nodes, the disease may rarely simulate tuberculosis clinically, but it should be remembered that tuberculosis of the inguinal lymph nodes is extremely uncommon; microscopic section of the lymph nodes closely resembles tuberculosis. Giant cells are frequently observed in venereal lymphogranuloma. However, one feature is apparently reasonably diagnostic; viz., a lymph node, removed in the proper stage of suppuration, will reveal microscopically tiny areas of caseation surrounded by a palisading of epithelioid cells. Such miliary abscesses may be round but are usually star-shaped. Pus obtained by aspiration from these suppurating nodes reveals no growth on culture and will, of course, not produce tuberculosis when injected into a guinea pig.

The disease may be confused with granuloma inguinale, in reality, only because of similarity in the terms. Granuloma inguinale is likewise a venereal disease, but it is manifested by ulcerations about the perineum which are rather superficial and do not attack the lymph nodes. Such ulcers may be located on the genitals or in the groin.

Treatment. Of the antibiotics, aureomycin (30 to 40 mg. per kg. per day) and chloromycetin (60 mg. per kg. per day) are the most effective. Penicillin is only slightly effective. Streptomycin is of no value (Long and associates) (14). None of these agents will be of value in treatment of strictures except for secondary perirectal infection. The infection of the inguinal lymph nodes is treated as a low grade inflammatory lesion. When suppuration appears, incision is recommended. On a few occasions mere aspiration of pus from the inguinal abscess has been sufficient to relieve symptoms and prevent further suppuration. Drainage of abscesses relieves the acute inflammatory manifestations but is by no means curative. Obstructive symptoms due to the stricture may often be combated with

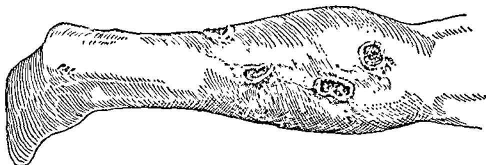

Fig. 15. Syphilitic ulcers (tertiary lesions). Note the punched-out appearance. Such ulcers are usually multiple and the discharge rather profuse.

problems that are encountered in gumma of the brain which, though rare, may present all the symptoms and signs of a brain tumor. Occasionally, visceral crises (in tabes), consisting of severe abdominal pain, simulate an acute intraabdominal surgical condition. In addition, however, to the presence of tabetic signs, a careful consideration will usually reveal a lack of muscle spasm, tenderness, leukocytosis, nausea, and vomiting, which would be present in an acute surgical process. Paretics are occasionally seen in the emergency room because of prostration and coma.

The tabetic bladder may result in a variable amount of incontinence and urinary retention, but infection is rarely significant unless induced by catheterization.

Treatment. The treatment of syphilis is not a surgical problem, but it should be emphasized that the superiority of penicillin over arsenic compounds has completely revolutionized therapy. Salvarsan now has only historic interest. Penicillin given in large doses for 10 or 20 days will cure over 90 per cent of cases, although involvement of the cardiovascular and cerebral nervous systems requires the care of a specialist because the residual damage is so severe that complicated therapy for a prolonged period is often necessary. Chloromycetin is also very effective in syphilis.

TUBERCULOSIS

The causative agent of human tuberculosis, *Mycobacterium tuberculosis*, was discovered by Koch in 1882. Two strains of *M. tubercu-*

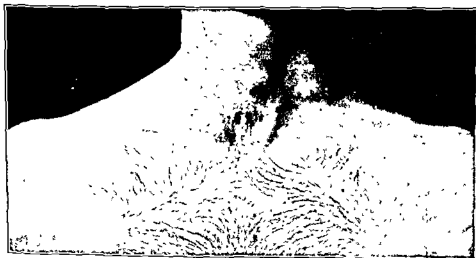

Fig. 16. Gumma of the right sternoclavicular joint in a young man, aged 28. Within a few weeks after the onset of intensive antiluetic therapy the swelling disappeared completely. (Washington University Clinic.)

Fig. 14. Gumma of forearm. Date of primary lesion unknown. The patient, a 45-year-old female, complained of a mass in the forearm which, under intensive treatment, rapidly softened and sloughed, leaving a deep ulcer as shown in the photograph. Healing was complete in a few weeks.

produce a perforation with a subsequent depression of the nasal bridge. Such deformities can only be corrected by plastic operations such as cartilage transplantation.

Gastrointestinal Tract. Syphilis of the stomach may produce clinical signs and radiologic findings similar to carcinoma of the stomach. The question of syphilis of the stomach always arises when manifestations of gastric ulcer or carcinoma occur in a patient with a positive Wassermann. Surgical excision of the ulcerated area is usually indicated because the cicatricial obstruction which follows chemotherapeutic healing will probably make operation necessary anyway. For that reason differential diagnosis is somewhat academic, except that differentiation from carcinoma is helpful or even necessary to aid in determination of the extent of resection.

Many years ago huge gummas of the liver were commonly seen and presented considerable difficulty in differentiation from intra-abdominal cysts and benign tumors which might justify operation. Due to modern chemotherapy, such lesions are rare. An acute syphilitic infiltration of the liver of the cirrhotic type, with the production of jaundice and other signs of portal obstruction, is more common.

Gummas were formerly thought to occur frequently in the terminal portion of the rectum and, after the diffuse scarring which follows the massive destruction of tissue, to terminate in a stricture. However, practically all strictures of the rectum are caused by lymphogranuloma inguinale (see page 112).

Skin. Reference has already been made to the primary and secondary lesions of the skin. More significant surgically are tertiary lesions (gummas) which appear in the subcutaneous tissues as indurated nodules, breaking down through the skin, forming ulcers. Such ulcers are usually punched out, occurring most commonly on the upper part of the leg, but they may be encountered any place on the body (Fig. 15).

Bones and Joints. Infection of bones, especially the long bones, is common and manifests itself in one of three ways: 1. periosteal form; 2. hyperplastic or associated with overgrowth; and 3. destructive. Joints may become involved (Fig. 16) to such an extent that disability is pronounced (Charcot's joint). These features are discussed in detail in Chapter 24.

Central Nervous System. The most common types of syphilitic invasion of the central nervous system are tabes and paresis, but these conditions do not present the surgical

Fig. 17. Suppurating tuberculous lymphadenitis of the femoral and inguinal nodes. Tuberculous lymphadenitis in this location is infrequent; the cervical and mediastinal nodes are involved most commonly. The patient is a Negro boy aged 11, who noted a fluctuant swelling in the femoral region. Six months previously, incision by a family physician resulted in the evacuation of an ounce or two of pus. The ulceration noted in the illustration developed since the incision. Total excision of the involved lymph nodes was carried out; complete healing occurred after two or three weeks. No other focus of tuberculosis was found at any time. Below the photo is a photomicrograph of the excised tissue, showing tubercle formation; note also the marked necrosis.

tubercles. On other occasions, ascites is more or less pronounced, and the intestines may be matted together with adhesions which may likewise surround caseous areas. Not infrequently, the disease may be much more acute and ushered in with symptoms suggestive of a subacute appendicitis. Treatment is really nonspecific, yet, for some unexplainable reason, definite improvement nearly always follows celiotomy even though a biopsy for microscopic diagnosis is all that is done.

Tuberculosis of the Bones and Joints. As previously stated, the bovine bacillus is probably responsible for invasion of the bone and usually attacks children or young adults rather than adults. Vertebrae are most frequently affected although the head of the femur is also commonly diseased. The most important feature in the treatment of tuberculosis of the bone or joint is rest and immobilization. A more detailed description of tuberculosis of bones and joints may be found in Chapter 24.

Genitourinary Tuberculosis. The most important organ of this system attacked by tuberculosis is the kidney. Destructive abscesses appear but frequently with no significant symptoms until the disease is implanted in the bladder, at which time frequency and urgency of urination appear. Red blood cells and pus cells, as well as tubercle bacilli, are found in the urine. Vague pains in the loin,

losis, the human strain and the bovine strain, can produce the disease in human beings; these were differentiated by Theobald Smith. The organism gains access to the human body by inhalation or by ingestion into the stomach. Considerable evidence has accumulated to suggest that most primary infections of the lymph nodes, which were known years ago as scrofula, are caused by the bovine strain. The same may be said about tuberculosis osteomyelitis of the long bones and hyperplastic tuberculosis of the cecum. These are commonly seen in the British Isles where pasteurization of milk is not widespread, but they are rarely encountered in the United States where pasteurization is general. It is assumed that the bovine bacillus, in contaminated milk, may penetrate the pharyngeal mucosa or tonsil, thereby infecting the cervical lymph nodes, and, by ingestion, give rise to certain types of alimentary tuberculosis. The fact that tuberculosis of the cervical nodes is decreasing as the practice of pasteurization of milk becomes more prevalent lends support to this theory.

The use of Kochs' Old Tuberculosis (OT) or of purified protein derivative (PPD-Siebert, 1934) may be helpful in diagnosis. A negative tuberculin test excludes active infection except occasionally in overwhelming infection or in the early stages (first two or three weeks) of the infection.

Tuberculosis is a large worldwide problem. The prophylactic efficacy of BCG vaccine (Calmette, Guérin, and associates, 1925) is still uncertain, although vaccines of slightly modified types are still being used with the hope that the disease may be thereby prevented. During the past several years, the death rate has decreased sharply because of the new agents used in therapy, but the incidence has decreased only slightly.

Pulmonary Tuberculosis. Surgical procedures may be extremely efficient in arresting the disease and encouraging healing. Phrenicectomy (avulsion of the phrenic nerve) paralyzes the diaphragm on the side of the operation and obtains rest for the affected lung; this rest is, of course, impossible if respiratory movements are normal. Perhaps a more efficient method of obtaining rest and immobilization of the lung is extrapleural thoracoplasty. Frequently, if the disease is confined to the apex, removal of the ribs over the apex (apical thoracoplasty) is sufficient to obtain the desired mechanical compression. For further discussion of the surgical therapy of pulmonary tuberculosis see Chapter 36.

Tuberculosis of the Lymph Nodes. As stated, involvement of the lymph nodes is uncommon in the United States, except in the chronic, calcified, asymptomatic form. Onset is usually insidious without constitutional symptoms. Cervical and mediastinal nodes are most commonly affected. The nodes in the axillary and inguinal region (Fig. 17) and in the intestinal mesentery are less commonly involved. For detailed description of tuberculosis of the lymph nodes see Chapter 26.

Intestinal Tuberculosis. Ulceration of the cecum (Fig. 18) may be produced by the tubercle bacillus and may clinically resemble carcinoma or idiopathic ulcerative colitis. However, roentgen examination with barium is of diagnostic aid if the lesion is in the sigmoid because tuberculosis rarely affects this part of the colon. The first symptoms of tuberculosis of the cecum are apt to be inconstant cramping pain in the abdomen associated with diarrhea of varying degree and possibly nausea and vomiting. If the ulceration is present throughout the entire colon, the symptoms may vary but little from those produced by a localized tuberculosis. In either case blood should be found in the stool. Intestinal tuberculosis is apt to be associated with, or secondary to, pulmonary tuberculosis, thereby adding considerably to its seriousness.

Occasionally, tuberculosis is demonstrable in microscopic sections of excised fistulous tracts resulting from ischiorectal abscess and may be the primary etiologic factor in the production of the abscess. In such instances there is usually an associated generalized tuberculous infection; it should be emphasized, however, that tuberculosis is found in a very small portion of the fistulas about the rectum and anus.

Tuberculous Peritonitis. Invasion of the peritoneal cavity is, of course, a secondary infection, primary perhaps to tuberculosis of the mesenteric lymph nodes, intestine, or Fallopian tube. The symptoms are extremely variable, and diagnosis is frequently made only at abdominal exploration. The intestines and omentum are commonly studded with

There are innumerable other regions where tuberculosis may develop, but most of them are so rare as not to be of great importance. Tuberculosis of the *larynx* is a slowly developing, painful disease, responding poorly to therapy. Invasion of the *skin* with the production of ulcers was common years ago but is rarely encountered now as a primary lesion. Tuberculosis of the *breast* occurs rarely; it is discussed in Chapter 35.

Treatment. The discovery of streptomycin by Waksman and Schatz in 1944 introduced a new era in the treatment of tuberculosis. Since then numerous other drugs including dihydrostreptomycin, neomycin, and viomycin have been employed. Unfortunately, the organisms tend to develop a resistance to these agents after several weeks of treatment. However, para-aminosalicylic acid (PAS) and isoniacid seem to decrease the degree of this resistance. For this reason, 1 gm. streptomycin twice weekly and 12 gm. PAS (in terms of free acid) daily is a common method of therapy. If sensitivity develops toward PAS, 0.15 to 0.3 gm. isoniacid may be given daily instead. Treatment should be carried out for 10 to 15 months. As stated, therapy with the drugs mentioned above has resulted in a much lower mortality rate but, as yet, has not greatly decreased the incidence of the disease.

TULAREMIA

This disease was first recognized by McCoy in 1911 as a plaguelike epidemic occurring in ground squirrels. A year later McCoy and Chapin isolated a bacillus which they called *Bacterium tularense* after Tulare County, California, where the epidemic was investigated. The reports of a few cases in human beings appeared at sporadic intervals, but it was not until several years later that the disease was described in detail and the name tularemia given it by Francis.

The disease is apparently prevalent in almost all the wild life of this country, especially in the rabbit, squirrel, ground squirrel, woodchuck, fox, and coyote. In animals, transmission is by a parasite, such as the tick, or by contamination of mouth lesions in carnivorous animals. The tick is the most common vector in army recruits; in civilians nearly 95 per cent of the infections are contracted directly from rabbits and nearly always while handling or dressing them. In most instances, a history of sustaining a minor injury of the hands during the process of cleaning the animal can be obtained from the patient. The occurrence of the infection in laboratory workers suggests that the organism may invade the unbroken skin and produce the disease. The disease is not contracted by eating infected rabbits, providing the meat has been thoroughly cooked. The incubation time varies in extremely wide limits but averages about six days. Natural immunity in human beings is apparently not common, as is corroborated by the fact that numerous laboratory workers coming in contact with the bacterium (now called *Pasteurella tularensis*) have contracted the disease. It seems probable that tularemia is destined to become more frequent, but fortunately the mortality is comparatively low, approximately 4 per cent.

Clinical Manifestations. The disease manifests itself clinically in six different clinical forms. 1. The *ulceroglandular* type is by far the one most frequently recognized. The onset is abrupt with the typical features of an acute systemic infection including fever, chills, prostration, anorexia, headache, backache, and occasionally delirium. The injury (usually on the hand), through which the disease was contracted, shows little tendency to heal and, by the time clinical symptoms appear, begins to ulcerate (Fig. 19). If the portal of entry is microscopic, a large, indurated, only slightly tender papule appears at this time. As the disease progresses the central portion becomes necrotic, and a superficial sinus or ulcer develops. Soon after the initial lesion reveals these signs of activation, the lymph nodes draining that area become enlarged. These nodes, situated in the epitrochlear and axillary regions, are discrete and even during the process of suppuration cause little tenderness or pain. Suppuration of one or more of these nodes usually occurs at one time or another during the course of the disease. The period of febrile reaction is short, except in the serious and fatal cases, but returns intermittently after intervals of several days. Symptoms of this type may be encountered 10 or 12 weeks after the onset of

Fig. 18. X-ray of patient (Negro man, aged 35) after injection of a fistulous tract in the right lower quadrant with Lipiodol, most of which has passed into the cecum.

mild fever, and malaise are common symptoms as the disease progresses. If the disease is unilateral, as may be determined by pyelograms, nephrectomy is indicated. Elimination of the focus of infection practically always eradicates the infection in the bladder (see also Chapter 40).

In women, the Fallopian tubes occasionally are infected. First, tubercles appear, but soon the fimbriated ends of the Fallopian tube become sealed off and the walls become thickened; caseous, thick pus is present in varying quantities. In the male, tuberculosis occasionally invades the epididymis, producing a mildly tender and painful organ which increases moderately in size and ultimately may break down and form a sinus extending through the scrotal wall. Removal of the epididymis yields satisfactory results. Occasionally the prostate and seminal vesicles are invaded.

Tuberculosis of the Central Nervous System. Invasion of the nervous system may manifest itself either as a meningitis, which, although of many weeks duration, is universally fatal, or as a tuberculoma. The latter lesion may produce symptoms identical to those encountered in brain tumor.

pulsive desire to run about aimlessly. He may become unusually affectionate but, with strangers, is apt to be irritable. Within a day or two he shows a desire to leave home, and it is during this period of two or three days, before paralyses set in, that he inflicts so much damage. The first group of muscles to become paralyzed are those controlling the lower jaw, which then drops and reveals profuse salivation. Paralysis of the hind quarters is usually followed in 24 or 36 hours by death. The saliva of the animal is infective four to six days before symptoms develop. The diagnosis in the animal is confirmed by demonstration of Negri bodies in the brain; these bodies are less readily found if the animal is killed before significant symptoms develop. Due supposedly to a natural immunity, only 20 to 30 per cent of people bitten by rabid dogs will contract rabies if untreated. However, since the mortality rate of the disease is so high, this offers no excuse for failure to give the Pasteur treatment if there is the slightest chance the animal was rabid.

Prevention. Injection of attenuated virus (Pasteur treatment) is by far the most effective prophylactic therapy. If there is the slightest possibility that the animal was rabid, the patient should be given this specific therapy. As first devised by Pasteur, it consisted of the injection of an emulsion made from a diseased spinal cord which was attenuated by drying for 14 or 15 days. Delay does not interfere with efficiency of the treatment until more than 12 to 14 days have elapsed since the patient was bitten. Opinions differ as to how the wound should be treated, but Shaughnessy and Zichis (16) have shown experimentally that washing the wound with soap and water is more effective in prophylaxis than using any cauterizing chemicals. In any case the wound should not be closed but should be left open.

Clinical Manifestations. The incubation period is variable, averaging 50 or 60 days, but may be as short as 10 days or as long as two years. Because of the fact that the virus apparently attacks chiefly nerve tissue and evidently makes its way to the spinal cord and brain through nerves, the *incubation time is shorter when the bite is inflicted on the face or trunk.* In man the disease is ushered in by an ungovernable restlessness and increased irritability and sensitivity to mild stimuli. He may suffer wild hallucinations and usually becomes maniacal soon after onset. Convulsions may be produced by the slightest stimulus, especially by draughts of air. As the disease progresses, hydrophobia is noted. This term is quite suitable because of the fact that, when the patient attempts to drink water, he is seized with such severe pain and laryngeal spasm that respiration may be impossible; the mere sight of water may bring on these attacks of suffocation and pain. After two to four days generalized paralysis develops; death follows inevitably and rapidly.

Treatment. Prophylactic therapy is effective as described above. After the development of the disease there is no known method of treatment which offers any hope of recovery. Symptoms are treated as they arise merely with the idea of making the patient comfortable. Convulsions and spasm should be controlled, if possible, by sedatives.

VINCENT'S ANGINA

Vincent's angina (trench mouth) is an acute inflammatory disease of the mouth, gums, or pharynx which is caused by a mixed infection of Vincent's fusiform bacilli and spirochetes. The lesion is really a form of stomatitis, may be multiple, and usually starts as a red edematous area in the center of which a small patch or ulcer develops. These ulcers are covered with a grayish white membrane and vary tremendously in size and depth, although they are usually shallow and no greater than 0.5 cm. in diameter. A moderate amount of tenderness and pain is present. The breath is foul. Secondary involvement of the cervical lymph nodes draining the area usually appears, but suppuration in the nodes is uncommon. The disease is usually of short duration, rarely presents a systemic reaction, and usually terminates in 8 to 16 days. Penicillin is most effective; large doses may be necessary. If this agent is ineffective, intravenous neosalvarsan should be tried.

NOMA

This is a rapidly spreading gangrenous process occurring usually in the gums, cheeks, and mucous membranes of undernourished children between the ages of 2 and 10 years.

Fig. 19. Ulcer of thumb due to tularemia. The *patient, a 36-year-old female, suffered a punctured* wound at this point five weeks previously while cleaning a rabbit. Three days later she had a chill and developed fever. A few days after this, the *ulcer on the thumb appeared*. Fever persisted, accompanied by an occasional chill. Four weeks after onset the epitrochlear and axillary nodes enlarged and were incised later because of suppuration. The *patient's serum agglutinated the Pasteurella tularensis* in a dilution of 1:160. (St. Louis City Hospital.)

the disease. 2. In the *oculoglandular* type, the primary lesion is in the conjunctiva, occasionally being found as a papule associated with edema, redness, lacrimation, and photophobia. Ulcerations are not uncommon. The auricular, submaxillary, and anterior cervical lymph nodes may enlarge and become moderately tender and painful. 3. A *glandular* type without evidence of a primary lesion is occasionally seen. In other respects, however, the symptoms and signs do not differ from those observed in the ulceroglandular type. 4. A *typhoid* type producing fever without a visible primary lesion or lymphatic involvement is uncommon. 5. The *pulmonary* type as a primary entity is quite rare but pulmonary infection is commonly encountered with other types of the disease, particularly the ulceroglandular type. 6. The *ingestion* type results from eating inadequately cooked infected rabbit meat. Diffuse pain in the abdomen, diarrhea, nausea, vomiting, and fever are usual symptoms of this type of infection; enlargement of the submaxillary and cervical lymph nodes is common. Moderate leukocytosis is usually present.

The Foshay test, consisting of the intradermal injection of a *P. tularensis* vaccine, is very accurate and is positive from the second day of the disease up to about 18 months. Unfortunately, the organism cannot be identified in smears from the ulcer; moreover, *P. tularensis* will not grow on the media routinely used for culture, but will grow in blood-glucose-cystine media. Guinea pigs can be infected readily with exudate and tissue from an infected case.

Antibiotics, including Streptomycin, Terramycin, and Aureomycin, are quite effective in treatment (14, 15). When suppuration appears at the site of infected lymph nodes, incision is indicated; drainage usually persists for many days or even for weeks.

RABIES

Rabies or hydrophobia is a spasmophilic or paralytic disease caused by a virus and contracted by the bite of a rabid animal. The dog accounts for more than 90 per cent of the human cases, but wolves, cats, badgers, and other animals may become infected and may also transfer the infection by their bite. Almost all animals, including horses and cows, are susceptible and may contract the disease if bitten by rabid animals. Although the disease is less prevalent now than it was 50 or 100 years ago, it will probably always be a menace as long as misdirected human kindness allows the stray dog to roam the streets and countrysides.

The greatest problem in rabies is determining whether or not the offending animal is rabid. This is usually not difficult. Healthy dogs are apt to bite but usually are guilty of this offense only during the excitement of play or while being tormented. The actions of a rabid dog are rather typical. The usual story is that the dog, a stray animal, deliberately ran up to the patient, bit him, and rapidly disappeared. If an attempt is made to follow these animals, it will usually be learned that more people have been bitten by the same dog. It is of extreme importance, then, that any dog that bites a person without provocation should be caught and confined under observation for 10 to 14 days. If the animal is rabid, serious symptoms (e.g., paralysis) will almost invariably develop within 48 hours. The onset of the disease in the animal is characterized by a restlessness and an im-

strated a spirochete (*Spirillum minus*) as the etiologic factor in the more common type known as Sodoku. A less common type known as Haverhill fever is caused by *Streptobacillus moniliformis*. About the same time the fever and associated symptoms develop, the scar at the site of the bite breaks down, ulcerates and a regional lymphadenopathy develops. The symptoms, which may include fever, nausea, vomiting, and pains in the joints and muscles, may be quite severe, resulting even in delirium. Fatalities, however, are uncommon. During the attacks a rather typical erythematous, macular rash with lesions as large as 1 to 2 cm. in diameter may develop. The attacks usually persist for two to three days but recur again in four to six days over a period of several months unless treatment is instituted. The spirochete may frequently be found in the blood, skin lesion, or lymph node of the patient, but it is more consistently found in the blood of a mouse injected with the blood of the patient.

Antibiotics should be effective in most cases. Altemeier and associates (17) have noted that the type caused by the streptobacillus responds to penicillin. Neosalvarsan is quite specific for the spirochetal type and should be tried if antibiotics fail.

ANTHRAX

A century or two ago anthrax was a miserable scourge in European countries, but during recent years it has become uncommon, especially in the United States. The causative organism, *Bacillus anthracis* (an aerobic, gram-positive, spore-forming bacillus), was isolated by Davaine in 1850. The disease is also known as malignant pustule or woolsorter's disease. Infection may be acquired by handling wool or hides from various animals, including sheep, cattle, horses, hogs, guinea pigs, and rabbits. In a few instances the source of infection has been found to be a newly acquired shaving brush.

There are three types of the disease: 1. The *cutaneous type*, which is associated with a low mortality, usually manifests itself as a furuncularlike lesion with a black necrotic center. 2. The *pulmonary* form of the disease is rare and presumably results from inhalation of the spores. The patient rapidly becomes very ill, develops chills, fever, prostration, tachycardia, cough, and pulmonary edema, and practically always dies within a few days after onset. 3. The *intestinal* form manifests itself by chills, fever, diarrhea, and vomiting and is associated with a high mortality.

The disease responds to penicillin, but, since an antitoxin is known to be effective, it should be given simultaneously. The lesions should not be incised because operative trauma seems to encourage development of bacteremia.

TYPHOID

Fortunately, typhoid fever is now a rare disease. Complications are common; most of them are surgical. *Perforation of an ulcer of the ileum* is perhaps the most common. Manifestations of the resultant peritonitis are atypical and consist of tenderness (without significant muscle spasm), increase in the distention, nausea, and occasionally vomiting. X-ray should reveal air under the diaphragm. Emergency operation is, of course, indicated. *Gallbladder disease including cholelithiasis* may be secondary to the disease. Typhoid carriers usually have infected gallbladders and/or "infected" gallstones, removal of which is curative on most occasions; "infected" gallstones may also be present in the common duct. These must also be removed in order to free the carrier of his hazard to others. *Osteomyelitis* and *chondritis* occur occasionally but are usually very insidious. Aureomycin should be given for all the complications since it is fairly specific for typhoid fever.

AMEBIC DYSENTERY

The primary lesion produced by *Endamoeba histolytica* (Fig. 21) is colitis, which develops as widespread ulcerations involving particularly the cecum, the ascending colon, and the upper rectum. The disease can usually be recognized by proctoscopy and microscopic examination of smears, which almost invariably will reveal amebae. Symptoms include abdominal pain (usually of a cramplike type), diarrhea, and occasionally nausea and vomiting. Accordingly, it may resemble the onset of acute appendicitis for which appendectomy may be performed. Such a

It is also known as cancrum oris or gangrenous stomatitis. Vincent's fusiform bacilli and spirochetes are frequently found in the tissue, but the exact causative organism is not known. Antibiotics, including penicillin particularly, should be tried. During recent years this disease has become extremely uncommon.

LUDWIG'S ANGINA

In 1836, Ludwig of Stuttgart described an acute, deep-seated infection involving the floor of the mouth and upper portion of the neck. Although the infection practically always remains localized in the floor of the mouth and upper part of the neck, constitutional symptoms, including fever, usually are present. The organism most frequently obtained on culture is a streptococcus, but other mouth organisms may be found, sometimes singly, but at other times apparently growing in a symbiotic manner. Anaerobic organisms undoubtedly play an important role in the development of the disease. The most common source of the infection is an alveolar abscess which ruptures through the inner table of the mandible (Ivy). The infection may arise from dental caries or other causes, but frequently no primary lesion can be discovered.

The induration and swelling of the floor of the mouth develop rapidly and are associated with pain but with a variable amount of tenderness. As the swelling increases, the tongue is pushed upward and backward, thereby holding the mouth open and interfering with swallowing and breathing. Redness of the skin does not appear until late. Fever is usually present as are also constitutional symptoms such as prostration and tachycardia, at least to a moderate degree. Edema of the glottis and bronchopneumonia are common and serious complications, especially in neglected or untreated cases.

Usually, the infection responds quite well to antibiotics; if not, radical incision will be indicated (Fig. 20). Even though very little, if any, pus may be found, incision appears to result in marked improvement. If at any time edema of the glottis or larynx occurs, a tracheotomy should be performed without delay. Too often, tracheotomy is not performed in time to be the lifesaving procedure that it should be.

RAT-BITE FEVER

Although it has been known for many years that a prolonged illness with intermittent attacks of fever may develop in the human being 10 to 22 days following a rat bite, it was not until 1916, that Futaki and associates demon-

developed; these are in turn converted into cysts identical to the original or mother cyst. Such daughter cysts also form granddaughter cysts, which are contained within a thick outer mother-cyst wall (Fig. 22).

The cysts enlarge and develop insidiously without many clinical manifestations. Rarely are systemic symptoms encountered. When the cyst is located in the liver, a mild, rather constant pain, similar to that produced by chronic cholecystitis, but without much dyspepsia, is experienced. Sometimes the cyst is palpable upon abdominal examination. If the cyst is in the lung, symptoms of a benign tumor, such as cough, mild pain on respiration, and dyspnea, may develop. Bone is not infrequently the site of invasion. Casoni's intradermal test* is usually considered the most important diagnostic procedure, although the echinococcus fixation test† of Weinberg is reliable. Both of these tests may give negative results when no absorption from the cysts is occurring. An eosinophilia is often present.

Unless inaccessible, the cysts should be re-

* Casoni's intradermal test is dependent upon sensitivity, as is the tuberculin test. A small quantity of fluid obtained previously from a known cyst is injected into the skin. A local reaction results if the patient has echinococcus disease.

† The complement-fixation test of Weinberg utilizes an antigen made from fresh hydatid fluid containing scolices. The test is performed on the patient's serum. The antigen required in this test may be obtained from some pharmaceutical houses.

mistake happened on numerous occasions throughout the country during the time when the Chicago epidemic of 1933 was at its peak. Submitting the patient to an operation during the onset of amebic dysentery will result in many fatalities even though the actual condition is recognized and emetine therapy instituted immediately.

Perforation of an amebic ulceration is not common but does occur; the most common sites are the cecum and appendix. In the chronic stage of the disease, stricture may develop, but it is quite uncommon. Another rare but important complication of amebic colitis is an *amebic granuloma,* which may be several centimeters in diameter and therefore resemble a carcinoma. It is most common in the cecum and upper rectum. If it is located in the rectum, diagnosis can be made by biopsy, since the organisms are invariably present in the involved tissue.

Abscess of the liver is a frequent complication of amebic dysentery, but it usually occurs only in the untreated or inadequately treated cases. The typical symptoms and signs of abscess of the liver, including chills, daily intermittent fever, prostration, and sweating, are usually encountered. Drainage by operation is associated with a high mortality, whereas intensive treatment with emetine alone will often prove curative. Aspiration is permissible in the large abscesses (see Chap. 28).

In the *treatment* of amebiasis, several drugs are effective. One of the most important is chloroquine, which should be given in doses of 0.6 gm. by mouth daily for two or three days, followed by a dose of 0.3 gm. daily for two or three weeks. Of the other drugs utilized, perhaps diodoquin and emetine are the more important. Antibiotics are usually indicated because of secondary infection which is so common; this is particularly true of amebic abscess of the liver. Indeed, the superimposed infection is an important factor in the high mortality rate.

ECHINOCOCCUS DISEASE

Hydatid or echinococcus disease is caused by one of the smallest of tapeworms, *Echinococcus granulosus,* and is encountered occasionally in most regions throughout the world but appears to be especially common in Australia, South America, and Iceland. Most of the patients with echinococcus disease encountered in the United States are foreign-born. For a detailed discussion of this disease the reader is referred elsewhere (18). The disease is contracted from dogs which are the tapeworm's host and excrete the eggs in their feces. After ingestion of the egg by the human being, the larva is freed by digestion of the shell and burrows into the intestinal wall. From there it may be carried in the portal blood stream to the liver, where it may lodge or be carried to or through the lung and finally to such organs as the kidney, bone, and brain. After larvae have reached their destination, hooklets disappear and a cyst develops, from the wall of which buds are

Fig. 22. Echinococcus cyst. This cyst was removed from the ventral surface of the liver in a man who was raised in Italy. Incision through the wall reveals numerous daughter cysts.

developed; these are in turn converted into cysts identical to the original or mother cyst. Such daughter cysts also form granddaughter cysts, which are contained within a thick outer mother-cyst wall (Fig. 22).

The cysts enlarge and develop insidiously without many clinical manifestations. Rarely are systemic symptoms encountered. When the cyst is located in the liver, a mild, rather constant pain, similar to that produced by chronic cholecystitis, but without much dyspepsia, is experienced. Sometimes the cyst is palpable upon abdominal examination. If the cyst is in the lung, symptoms of a benign tumor, such as cough, mild pain on respiration, and dyspnea, may develop. Bone is not infrequently the site of invasion. Casoni's intradermal test* is usually considered the most important diagnostic procedure, although the echinococcus fixation test† of Weinberg is reliable. Both of these tests may give negative results when no absorption from the cysts is occurring. An eosinophilia is often present.

Unless inaccessible, the cysts should be re-

moved as soon as discovered. If possible the entire outer cyst is removed, avoiding rupture if possible, because of the danger of implantation of the contents of the cysts. Another undesirable feature of rupture of a cyst during its removal is the possible development of a sensitivity which may result in an anaphylactic reaction if a second operation is required and another cyst ruptured. In any event, if a subsequent operation is required for removal of more cysts, it is desirable to give hydrocortisone or cortisone on the day of operation to prevent an anaphylactic reaction. When in the liver, it is usually impossible to remove the outer cyst wall because of the danger of hemorrhage. Under such circumstances, the contents should be removed without peritoneal contamination, if possible, and 4 per cent formalin or tincture of iodine should be painted on the wall of the cyst to destroy the membrane. If all the cysts are removed and the lining of the mother cyst is destroyed, recovery should be uneventful and permanent (Fig. 22).

GRANULOMA INGUINALE

In 1905 Donovan described an intracellular microorganism which, on a stained (Wright) smear obtained from the lesion, shows up as a small, round, pink body with a blue-staining coccoid center. He associated the organism (*Donovania granulomatis*) with granuloma inguinale, but it is not agreed that this is the etiologic factor. The disease is of venereal origin, occurs more often among Negroes, and was originally described as a tropical disease, although it is encountered occasionally in temperate zones as well. In males, the lesion usually starts on the penis or scrotum, but frequently the initial lesion is in the groin (Fig. 23). In females, the lesion is first seen on the vulva, perineum, or groin. The disease starts as an indurated papule which ulcerates and slowly involves the adjacent skin. The granulating tissue of the ulcer is elevated, especially at the edges, appears red, and seldom reveals a necrotic base. Occasionally healing occurs in the center, either as a rough scar or combined with epithelization made possible by islands of epithelium which escaped destruction by the ulcer. At times the entire penis may be destroyed if treatment is not started in time. The lesion remains superficial and shows no tendency to develop sinuses or to invade the lymph nodes. The ulceration produces a thin milky secretion which at times has a characteristic sour fetid odor. Very little pain or tenderness is present. Occasionally the disease spreads toward the anus and produces a fungating, somewhat papillomatous lesion.

In therapy, aureomycin or terramycin should be tried first. If these agents are not effective, tartar emetic should be given, since it is fairly specific for this disease; a dose of 3 to 5 ml. of a 1 per cent solution should be given every three or four days and increased

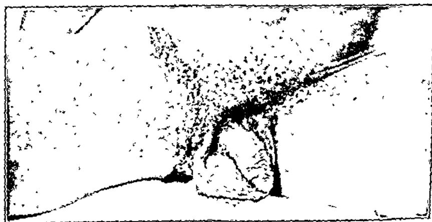

Fig. 23. Granuloma inguinale. The lesion, in a 45-year-old colored male, was cured by the administration of tartar emetic but recurred a few months later. The recurrent lesion was not as extensive as the original ulceration but responded scarcely at all to tartar emetic and various other types of therapy.

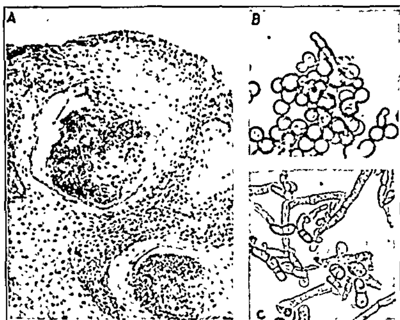

Fig. 24. Blastomycosis. A, minute blastomycotic abscess (low power) in skin at border of lesion illustrated in Figure 25; B, appearance of blastomycetes suspended in saline after first culture (high power); C, after several subcultures; note the mycelial formation. (From Cole. Ann. Surg.)

to 8 or 10 ml. as tolerated. Treatment should be continued until the patient has received 12 to 15 injections. Meticulous cleanliness is also important; hospitalization in stubborn cases for frequent irrigation is sometimes advisable.

BLASTOMYCOSIS

This disease was described independently in 1894 by Gilchrist and by Busse as being caused by a yeastlike organism, *Blastomyces dermatitides.* This organism multiplies in the tissue by budding, but develops mycelial threads (19) when growing in culture (Fig. 24). The cells are about 8 to 10 μ in diameter and are readily identified by the double refractile capsule. They have no nucleus, but the protoplasm contains coarsely granular material with refractile bodies. The organisms are most readily found by application of a small drop of 10 per cent sodium hydroxide to some pus under a cover slip in a fresh unstained preparation.

The lesion usually becomes implanted in the skin by a minor injury and manifests itself either primarily as an ulcer at the site of the inflicted wound or as a papule which breaks down and forms an ulcer. This ulcer starts originally as a local lesion and soon assumes characteristics which in appearance can be confused only with one other disease, lupus vulgaris (tuberculosis). The surface of the lesion is ulcerating, is raised above the adjacent skin, and assumes a cauliflowerlike or papillomatous appearance (Fig. 25). Along the edges of the ulcers may be found tiny pinpoint abscesses which sometimes may be seen only with the aid of a lens. The organisms are most readily found in these tiny abscesses. This lesion may remain local for one to two years, but it tends to become systemic partly because of autoinoculation but more especially because of metastatic implantation by the organism. The lungs are usually the first to become secondarily infected. Occasionally the infection is primary pulmonary. From the clinical and radiologic standpoint the infection of the lung cannot be distinguished from tuberculosis, but the organisms may be found in the sputum. Almost any organ in the body may become infected. The diagnosis is confirmed by finding the organisms, but when there is doubt, the patient should be tested with the antigen, blastomycin.

Treatment is so unsatisfactory that very few patients who develop the systemic disease ever recover. Unless the local lesion is seen or recognized early enough to permit complete excision, it will lead to a systemic in-

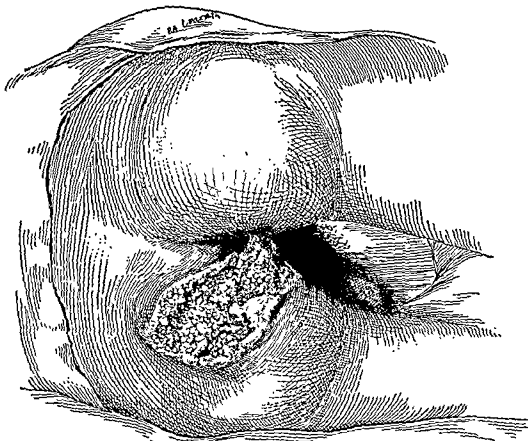

Fig. 25. Blastomycosis. Note the cauliflowerlike surface. The patient, a young man, suffered an injury to a finger while working in a mine. This ulcer failed to heal. Several months later lesions developed in the skin at numerous places over the body, including the buttock as shown above. In spite of various types of therapy, including administration of potassium iodide, x-ray therapy, and local medicinal application, the patient slowly failed and died two and a half years after onset. (Drawn from Cole. Ann. Surg.)

fection. Accordingly, we then *emphatically recommend excision* if the disease has not spread systemically. Stilbamidine and propamidine (aromatic diamidines) have been reported by Schoenbach and associates (20) as being quite effective in this disease. *Sodium iodide in large doses is helpful* but by no means curative.

CHANCROID

A chancroidal ulcer is of venereal origin, appears either on the penis, vulva, or vagina, and is caused by the Ducrey bacillus (gram-negative) which was isolated in 1889. The disease is autoinoculable and for that reason may occur as multiple ulcers. Diagnosis can usually be made readily by the presence or *history of a large primary ulcer on the genitals* associated with a painful and tender lymphadenitis in the groin. The use of Dmelcos vaccine, which is a suspension of killed Ducrey bacilli, as a diagnostic test may be extremely helpful in doubtful cases. In this test 0.2 ml. of the vaccine is injected intracutaneously in the forearm; a local reaction (papule or pustule) 48 hours after injection is a *positive* test. Four to eight days after exposure, a tiny *pustule appears which develops into an ulcer* (Fig. 26) several days later. From the ulcer, the edges of which are soft, friable, irregular, and slightly undermined, a foul profuse discharge appears. The primary lesion heals within two to four weeks, but unilateral or bilateral inguinal lymphadenitis (bubo) usually develops. Differentiation from venereal lymphogranuloma has been discussed on page 113. *Frequently, secondary infection is* shown by an increase in the acute inflammatory reactions; pyogenic bacteria will be obtained from the pus on culture. Culture of the causative organism from the ulcer requires special technic. Frequently, aspiration of the

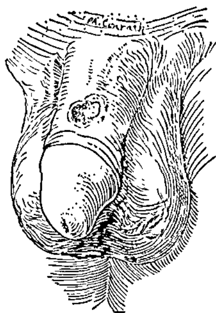

Fig. 26. Chancroid of the penis. The ulceration may be widespread, multiple, and on rare occasions very destructive.

pus in the suppurating lymph nodes is sufficient to allow the process to subside. At other times, incision and drainage is necessary. Treatment with sulfathiazole or sulfadiazine is quite effective. Antibiotics may be tried, but the disease is resistant to penicillin.

RARER TYPES OF MISCELLANEOUS SURGICAL INFECTIONS

Coccidioidal Granuloma. The causative agent is a yeastlike organism which reproduces by sporulation, in contrast to the blastomycete which reproduces by budding. When the sporozoites are mature they escape to the outside by bursting through the capsule. The disease was apparently first described by Wernicke in 1892. The organism produces nodules or a pustular, granulomatous eruption anywhere on the skin. Various organs of the body are invaded in a manner similar to blastomycosis but perhaps with more resemblance to tuberculosis. It was originally thought that the disease was universally fatal, but it has been noted recently that cures or survival for many years are common. In this country most of the cases are seen in California and Texas. It was commonly observed among troops training in California for desert warfare during World War II. The pulmonary type predominated, but, contrary to expectations, the mortality was low, influenced perhaps by early treatment and minimizing exposure. Diagnosis may be aided by the antigen coccidioidin. No medical agents are very effective in therapy.

Sporotrichosis. The etiologic factor is *Sporotrichum schenckii,* which may readily be found in smears of pus obtained from the lesions. The characteristic feature of the disease is the formation of soft, mildly inflamed nodules which appear in a chainlike fashion along the course of the lymphatics, particularly of the arms and legs. These nodules vary from 0.5 to 1 cm. in diameter and may break down and suppurate. A primary lesion may be absent but, if present, may readily be confused with tularemia. Few constitutional symptoms appear, but occasionally bone may be involved. The oral administration of potassium iodide, increasing the dose to 150 or 200 drops of saturated solution per day is very efficient in eliminating the disease.

Cryptococcosis (Torula Meningitis). In 1916 Stoddard and Cutler reported a group of patients with symptoms suggesting brain tumor or tuberculosis meningitis but in whom autopsy findings revealed an unusual type of meningitis caused by a yeastlike organism, *Cryptococcus histolyticus* (*Torula histolytica*). The organisms vary tremendously in size. Some are doubly contoured. The larger ones contain a dark-staining chromatinlike substance which resembles a nucleus. Reproduction is by budding. The organism attacks the brain by producing a thickening of the piarachnoid associated with tiny vesicular nodules containing clear liquid material. Larger caseous nodules may often be found within the brain itself. In one of the three cases observed in Barnes Hospital, St. Louis, an ulcer of a toe (Fig. 27) had been present several weeks before development of the cranial symptoms and apparently was the primary lesion. If an ulcer is present, the diagnosis can usually be made by finding the fungus on smear, by culture, or animal inoculation. No effective treatment is known. Broad spectrum antibiotics should be tried.

Yaws. With manifestations similar to syphilis, this disease is likewise caused by a spirochete (*Treponema pertenue*). The response to the serologic tests is almost identical to

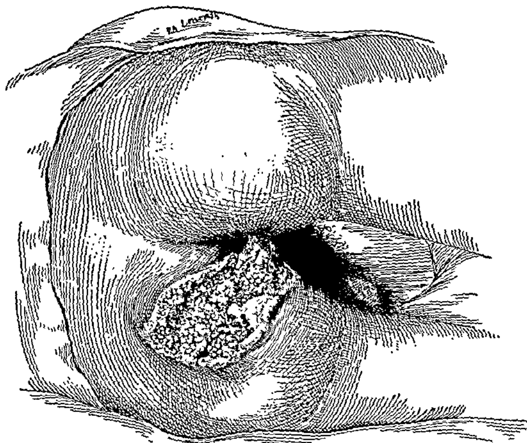

Fig. 25. Blastomycosis. Note the cauliflowerlike surface. The patient, a young man, suffered an injury to a finger while working in a mine. This ulcer failed to heal. Several months later lesions developed in the skin at numerous places over the body, including the buttock as shown above. (Drawn from Cole. Ann. Surg.)

fection. Accordingly, we then *emphatically recommend excision* if the disease has not spread systemically. Stilbamidine and propamidine (aromatic diamidines) have been reported by Schoenbach and associates (20) as being quite effective in this disease. Sodium iodide in large doses is helpful but by no means curative.

CHANCROID

A chancroidal ulcer is of venereal origin, appears either on the penis, vulva, or vagina, and is caused by the Ducrey bacillus (gram-negative) which was isolated in 1889. The disease is autoinoculable and for that reason may occur as multiple ulcers. Diagnosis can usually be made readily by the presence or history of a large primary ulcer on the genitals associated with a painful and tender lymphadenitis in the groin. The use of Dmelcos vaccine, which is a suspension of killed Ducrey bacilli, as a diagnostic test may be extremely helpful in doubtful cases. In this test 0.2 ml. of the vaccine is injected intracutaneously in the forearm; a local reaction (papule or pustule) 48 hours after injection is a positive test. Four to eight days after exposure, a tiny pustule appears which develops into an ulcer (Fig. 26) several days later. From the ulcer, the edges of which are soft, friable, irregular, and slightly undermined, a foul profuse discharge appears. The primary lesion heals within two to four weeks, but unilateral or bilateral inguinal lymphadenitis (bubo) usually develops. Differentiation from venereal lymphogranuloma has been discussed on page 113. Frequently, secondary infection is shown by an increase in the acute inflammatory reactions; pyogenic bacteria will be obtained from the pus on culture. Culture of the causative organism from the ulcer requires special technic. Frequently, aspiration of the

injury or abrasion. They may occur at the site of penetration of larvae such as hookworm or strongyloides associated with secondary infection. In some cases the abrasion can be traced to the myiasis-producing fly which deposits its eggs under the skin; in a variable number of weeks, depending on the type of fly, the larvae burrow to the exterior and produce an ulcer which is apt to become secondarily infected. The initial lesion is painful and papillomatous in character, becomes necrotic, and ulcerates. These ulcers may become multiple and enormous in size; they heal slowly and usually with a deforming scar. Penicillin and a well balanced diet are quite effective.

The type of ulcer designated as Oriental Sore (also known as Delhi Boil, Bagdad Boil, and so forth) is caused by *Leishmania tropica* and is transmitted by sandflies (*Phlebotomus papatasiiand Pisergenti*). It is encountered in tropical regions of both hemispheres. After an incubation period of several weeks or months, a small indurated crusted nodule appears at the site of the bite, usually on the exposed parts of the body, and, within a period of several weeks, progresses to ulceration. Multiple lesions are common. Likewise, secondary infection is common and may increase the size of the ulcer, as well as its symptoms. The uncomplicated sores heal within 2 to 10 months but leave depigmented scars, often with retraction and deformity. A fairly solid immunity follows this infection. Treatment consists of injection of quinacrine and berberine sulfate around the ulcer; sodium antimony gluconate should be given parenterally. If secondary infection is extensive, penicillin or a similar antibiotic should be given.

Histoplasmosis. Histoplasmosis has been recognized only comparatively recently, but, in view of its similarity to certain infections (particularly tuberculosis), it is probably an old disease. The causative organism is the fungus, *Histoplasma capsulatum,* which grows readily in proper media. Since histoplasmosis is air-borne, the pulmonary system is most frequently involved. Fever, occasional chills, cough, sweating, malaise, headache, arthralgia, and myalgia are apt to begin 10 days to 3 weeks after inhalation of the fungus. In the acute stage, pulmonary findings are minimal. Other manifestations such as ulcers (in the mouth, pharynx, or intestine), weight loss, and anemia may develop. The appendix may also be involved and produce manifestations of appendicitis. Enlargement of the liver, spleen, and lymph nodes likewise is common. Bone may be affected, in fact, so commonly, that bone-marrow aspiration will reveal presence of organisms in a high percentage of cases. In advanced cases, cavities form in the lung; on such occasions, the disease is difficult to differentiate from tuberculosis except by the tuberculin and histoplasmin tests. The antigen, histoplasmin, originally prepared by Christie and Peterson (23) (obtainable from the National Institutes of Health), as well as a recently devised complement-fixation test, is quite accurate in diagnosis. The disease is most commonly seen in children and young adults in the central states. In the mild form, it occurs as diffusely calcified nodules in the lungs, as revealed by x-ray. With the use of histoplasmin and culture methods, the diagnosis can usually be made if the disease is suspected. There is no specific agent for treatment although mycostatin, amphotericin and ethyl vanillate should be tried (24). Even without treatment most patients recover, although the illness may extend over a period of many months.

Nocardiosis. This is a term applied to various diseases caused by some species of the genus *Nocardia,* which are gram-positive rods with branching filaments; they are of the family Actinomycetaceae. The organisms occur freely in nature, but not all are pathogenic to man. *Pulmonary nocardiosis* resembles tuberculosis clinically and roentgenologically. The organisms may attack the brain, bones, and, in fact, almost any organ of the body.

Madura foot may be classified as a nocardial infection; it is caused by *Nocardia madurae.* The characteristic lesions are slowly forming nodules which occur usually on the plantar surface of the foot. These nodes become soft and later form sinuses which penetrate so deeply as to involve any of the bony or soft tissues of the foot; amputation may be required. While madura foot (mycetoma) is encountered chiefly in the Orient, especially among poorly nourished Indians, it does occur in the temperate zones. The diagnosis may often be made by finding the organ-

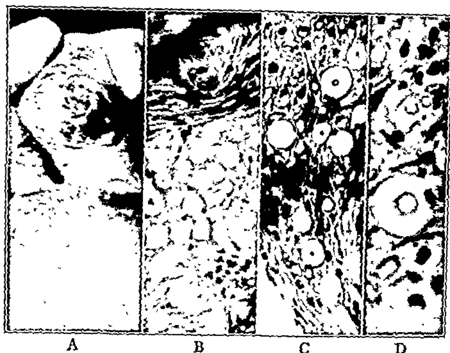

Fig. 27. Torula. A, photograph of the under surface of the second toe, showing the ulcer due to torula. Patient died four months later, six months after the appearance of the ulcer and the development of symptoms typical of torular infection of the brain; B, C, and D, microscopic section (high power) of the ulcer, which was excised, revealed many torula organisms which characteristically vary considerably in size, staining qualities, and so forth. D is slightly higher power than B and C, and shows the doubly contoured characteristic which is frequently noted, thereby simulating a blastomycete.

syphilis. It is not a venereal disease; infection usually occurs through a wound of the skin. The disease is common in Africa, India, and parts of South America but is rarely seen in this country. Primary, secondary, and tertiary stages are encountered with ultimate invasion of many organs, including bone, unless treatment is instituted. Arsenic in the form of salvarsan or neosalvarsan is specific, but penicillin is equally effective.

Leprosy. This disease was a serious scourge centuries ago, but it is rarely seen now except in the leper colonies. The most common lesion is a hyperemic nodule of the skin which may suppurate and produce prominent deformities because of cicatrization. On rare occasions, entire fingers or toes may be destroyed by the ulcerative process. Numerous internal organs may become affected. The disease resists treatment and may condemn the patient to isolation for the duration of his life. The victims usually live for years but may die from intercurrent infection. Patients with the disease should be isolated, although the contagious quality of the disease has been greatly exaggerated.

Numerous medicinal agents including the newer antibiotics are being utilized in therapy with variable effect, but none is specific.

Mycosis Fungoides. This is a chronic granulomatous disease possibly of parasitic origin which manifests itself as soft reddish nodules on the skin. These nodules may disappear or ulcerate with the production of a fungoid tumor. Lymph nodes and internal organs may become involved. The mortality is high.

Tropical Ulcers and Sores. These lesions are of numerous types; the etiology of many is poorly understood. However, most authorities (21, 22) in tropical medicine prefer to divide them into two major types: (1) Tropical Ulcer and (2) Oriental Sore.

The so-called Tropical Ulcers are of uncertain etiology. They may be caused by numerous bacteria particularly the spirochete (*Treponema vincenti*) and the fusiform bacillus (*Bacillus fusiformis*). They are chronic, progressive sloughing ulcers usually seen on the lower extremities. The size varies greatly often reaching 5 to 10 cm. in diameter. These ulcers commonly develop at the site of an

8

ULCERS AND GANGRENE

CARL MOYER

Ulcers
Gangrene

Ulcers, or sores, and gangrene are intimately related. All ulcers excepting those that follow the avulsion of tissue are preceded by necrosis or gangrene of the skin.

Gangrene once implied massive necrosis of tissue but now necrosis of any part of the living body may rightly be called gangrene. Nonetheless some practical distinction still remains: the ulcer follows limited gangrene while loss of life or limb still attends massive necrosis or gangrene.

Clearly the causes of gangrene and ulcer are identical: namely, trauma, infection, and inadequate nutrition of a part of the body by virtue of impedence of blood flow or hemic abnormalities. However, because the therapeutic problems posed by massive necrosis and ulcers differ so much, this chapter is divided into two parts, Ulcers and Gangrene.

Excepting for the self-inflicted traumatic ulcer, the factitious ulcer, the relationship of trauma to gangrene and ulcer will be discussed in the section on Gangrene.

ULCERS

Although much has been written about the specific appearances of certain ulcers, excepting for a few, such as the relatively rare blastomycotic, maduromycotic, tularemic, and chromoblastomycotic ones, there is often nothing characteristic about them. The neoplastic ulcer may have a relatively clean granulating base without a rolled-up edge, the stasis ulcer may have an appearance varying from a pale avascular base with heaped-up edges to a highly vascular base with flat edges; the same is true for the arterial occlusive ulcers. The determination of the cause of an ulcer must rest upon the discovery of specific objective evidence and not upon its gross appearance.

Because the proper treatment of an ulcer primarily depends upon the solution of the problem of its *genesis*, the determination of the nature of an ulcer is most important. Occasionally, this is difficult unless an orderly approach to the problem is made.

The parts of the history and the examinations of the person that are particularly pertinent to the ulcer problem are as follows:

History:

1. Relationship of the onset to injury, cold, heat, general illness, and to thrombophlebitis.
2. Medications used particularly locally.
3. Occupation, especially in regard to the handling of animals, animal products, exposure to cold in refrigerators as well as outdoors.
4. Foreign travel and length and nature of sojourn.
5. Patient's description of the local lesion before the ulcer occurred.
6. Ascertainment of the characteristics of the pain and amount of itching.

Examination:

1. Culture
   a. for corynebacteria on Loeffler's and tellurite media.
   b. for hemolytic streptococci and coagulase-positive and hemolytic staphylococci.
2. Biopsy of edge and base of ulcer.
3. Determination of patency of arterial system (oscillometry and angiography when any peripheral pulses are absent).

ism in the discharge from the sinuses in the foot. In this country at least, the chief importance lies in its similarity to tuberculosis and other chronic osteomyelites of the foot.

Treatment of most types of nocardiosis is unsatisfactory. However, some types respond to chloramphenicol and sulfadiazine. Very large doses of penicillin should be tried.

tibacterials will, in some sensitive individuals, maintain the ulcer. Coal oil (kerosene), turpentine, and tar, still used as home-remedies for itches, rheumatic pains, and insect bites, are other chemicals that are capable of making an ulcer out of an otherwise simple cut or abrasion.

The treatment of a factitious ulcer is usually simple: Remove the cause. However, at times, the ulcer has existed for so long that its base is so avascular that excision of the ulcer and skin grafting are needed to cure it.

Bacterial Ulcers. Globally, bacteria, fungi, and protozoa constitute the major causes of ulcers. However, in the United States and Canada they are not as important etiologically as they are in Asia, Africa, and tropical America. Nonetheless one should be more mindful of the roles that they play in the genesis of ulcers because of the facilitation of travel and the increasing temporary abode of many of our people in Asia, Africa, and tropical America.

Corynebacterium diphtheriae, Pasteurella tularensis, and anaerobic streptococci are important causes of cutaneous ulcers. Corynebacterial infections of wounds of the legs in the tropics produce chronic Tropical Sores and in the temperate zones ulcers that are almost uniformly mistaken for stasis ulcers. Chronic diphtheritic ulcers have no specific characteristics and are not as a rule attended by systemic illness. The only means of detecting them is by the routine culturing of the exudate from all chronic ulcers on Loeffler's and tellurite media. The discovery of a positive culture should be followed by virulence tests. The treatment of a diphtheritic ulcer consists of meticulous cleanliness and antitoxin. Rigid aseptic precautions are important and, if in a hospital, the patient must be isolated.

Tularemic ulcers are small, 0.5 to 1 cm., and heal spontaneously within three to six weeks (p. 121). They occur at the sites of inoculation of the organism. Inoculation may be effected through an abrasion or cut of the hand while skinning or cleaning infected rabbits or ground squirrels and by the biting deer-fly or tick. The ulcer develops rapidly and is peculiarly painful. The lymph nodes in the lymphatic drainage area of the inoculation site enlarge rapidly and painfully and are prone to suppurate. The systemic illness, though usually marked, may be very slight. Diagnosis before the third week of the illness depends upon recognition of the significance of the association of the small, painful ulcer and lymphadenitis of the regional lymph nodes, and the history. After the second week of illness, specific agglutinating antibodies appear in the blood. Streptomycin, 1 gm. daily, cures the disease. However, lymph nodes may suppurate and require drainage when streptomycin is started later than the third day of the illness.

The anaerobic streptococci that are a part of the normal bacterial flora of the mouth and gastrointestinal tract occasionally cause peculiar chronic ulcers (Fig. 2). Although the anaerobic streptococcal ulcer usually begins with an infection of an incision through the abdominal wall, it does follow even minor injuries to any part of the body. The chronic anaerobic streptococcal ulcer has purple, rounded margins with undermined edges (1) and sinuses that often communicate with satellite ulcers about it and occasionally follow intermuscular fascial planes and large blood vessels. It grows in size steadily unless properly treated.

The most effective treatment of the anaerobic streptococcal ulcer developed to date is the incision of the undermined margins and all sinuses, so as to permit loose packing of the whole of the infected zone twice daily with fine-meshed gauze impregnated with a suspension of activated zinc peroxide, and the administration of penicillin. Split-thickness grafts are often required to cover the cutaneous defects after the infection is controlled.

Acute ulcers associated with pyogenic bacteria (especially the streptococcus) may develop anywhere on the body, primarily on the lower extremity (Fig. 3). They are probably usually secondary to mild trauma which would heal uneventfully if contamination with a virulent organism had not taken place. They tend to heal spontaneously after the infection subsides. They are less common now than before the days of antibiotics.

Fungal Ulcers. *Blastomyces dermatitidis* (U. S.) and *B. brasiliensis* (tropical America) when introduced into injured skin or mucous membranes are capable of producing chronic ulcerative granulomas of the skin,

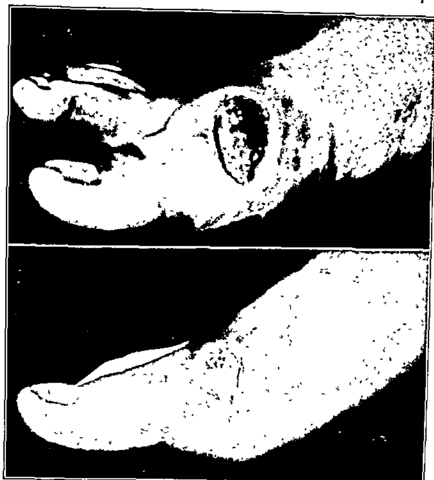

Fig. 1. Traumatic ulcer due to repeated chemical injury. The top figure shows an ulcer produced by daily application of carbolic ointment for four weeks following a small laceration of the foot in a girl eight years old. Below, within three weeks after elimination of the chemical irritation, the ulcer had healed.

4. Biopsy of skin and muscle at some distance from the ulcer whenever Raynaud's phenomenon is observed.
5. Red blood cell count.
6. Tests for red blood cell sickling in all Negroes with ulcers of the lower extremity.
7. Platelet counts on all persons having ulcers of the legs with deep pigmentation of the skin about the ulcer and around the entire leg.

The exercise of thought after ascertaining these things, and repetitive observation and reflection will unravel the etiology of most ulcers and permit the selection of the appropriate means of treatment.

Factitious Ulcers. Proving that an ulcer has a factitious (man-made) origin is frequently difficult more especially when the patient willfully makes it. The factitious ulcer has no telltale characteristics. It is usually chronic and located upon the anterior or lateral aspect of the lower extremity. Willful factitious ulcers are usually produced by the individual burning, rubbing, or scratching himself. The factitious ulcer is to be found most often among prisoners, the insane, and "professional workmen's compensation cheats." Because the ulcer is most frequently maintained by scratching with the fingernails, testing the debris beneath the fingernails daily for the presence of blood often provides a clue to the patient's actions.

The nonwilled factitious ulcer is much more common than the willed and is usually readily diagnosed. The history is most important: a scratch, cut, or insect bite upon which a salve containing a medicament or a home-remedy is placed is the usual beginning of such an ulcer. Salves containing phenol are especially potent ulcer producers (Fig. 1). However, ointments containing such things as picric acid, penicillin, Furacin, and other an-

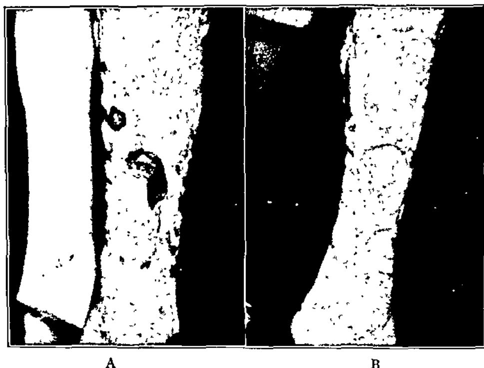

Fig. 4. Syphilitic ulcers of the leg; such ulcers are usually multiple. A, note the smooth, punched-out appearance of the edge of the ulcer. As happens occasionally, antiluetic treatment was ineffectual. B, appearance of leg three weeks after excision of the ulcer and application of skin graft.

sent local disease only and their removal is curative. Occasionally, a second excision may be required. X-ray therapy has been recommended and is fairly effective, but the treatment is prolonged (75 to 100 roentgen units filtered through 1 mm. of aluminum weekly for 12 to 15 weeks) and entails the danger of delayed carcinogenesis.

Miscellaneous Ulcers—Microorganismal. Granuloma inguinale having as its causative agent the Donovan body, a gram-negative nonmotile organism, is a *chronic ulcerative* destructive disease mainly of the crural regions and genitalia. However, lesions about the neck, hands, and face are frequent: rarely they are to be found upon the legs.

When not severely secondarily infected, the ulcer of lymphogranuloma is peculiarly painless. It bleeds very readily. The periulcerous *swelling often is great and has all of the* visible and palpable characteristics of chronic hard lymphedema.

Microscopic examination of a biopsy taken from the margin of the ulcer usually permits a ready diagnosis because of the typical intracellular position of the Donovan bodies in large mononuclear cells. However, even though the organism may not be found in the first biopsy, the exceedingly rich vascularity of the granulation tissue should prompt suspicion of the nature of the ulcer and biopsy repeated until the organism is found.

Streptomycin (4 gm. daily for 10 days to 3 weeks) is curative. Occasionally operative correction of scar contractures may be required after streptomycin has cured the disease.

The chronic, cutaneous, syphilitic ulcer is a manifestation of late syphilis and represents the breakdown of a cutaneous gumma. Consequently, a painless cutaneous tumor precedes the ulcer. The syphilitic ulcer is painless, sharp-margined (Fig. 4) and soon covered by a plush, healthy looking granulation tissue that accepts split-thickness grafts readily. After ulceration has occurred, diagnosis cannot be established with certainty by biopsy. Diagnosis largely depends upon clinical suspicion and the institution of a therapeutic trial. Any ulcer that is preceded by a painless tumor should be considered to be a leutic

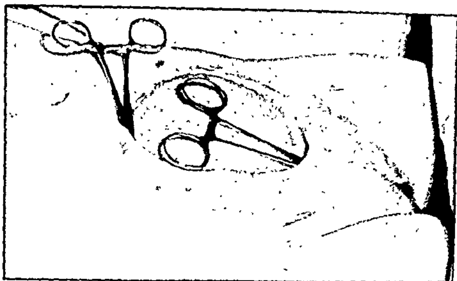

Fig. 2. Chronic undermining ulcer of Meleney, produced by a microaerophilic hemolytic streptococcus. The photo represents the ulcer on admission, one year after onset of illness. Note the extensive undermining extending into the vulva and into the flanks. The skin edges were rolled in. Counter incisions had been made in the groins. (From Meleney. Ann. Surg.)

and skin and oronasal mucous membranes respectively. In the United States, blastomycotic ulcers are found mainly upon the ankles, legs, feet, face, hands, and wrists. The ulcer grows slowly. Its margin is irregular, raised, and contains small abscesses having minute external openings exuding small amounts of pus. The central part of the ulcer heals, as the margin extends, and is covered by atrophic nonpigmented skin lacking accessory skin structures. The diagnosis is fairly easily made by biopsy of a part of the margin of the ulcer containing one of the small abscesses, culture of the pus from a satellite abscess on Sabouraud's media, and skin testing with blastomyces vaccine.

Excision of the entire ulcer and secondarily healed central area and immediate coverage of the cutaneous defect with a split-thickness skin graft after desensitization of the individual with blastomyces vaccine quickly cure most blastomycotic ulcers provided they are not associated with the systemic form of the disease. Fortunately, most of the ulcers repre-

Fig. 3. Pyogenic ulcers due to a streptococcus infection. The above photograph was taken five weeks after onset at the site of minute abscesses which failed to heal, presumably because of dependency and the virulence of the organism.

The protozoans *Leishmania tropica* and *L. braziliensis* are prominent causes of chronic cutaneous ulcers (Oriental Sores) in the tropics and semitropics wherever tropical sandflies exist. The disease is not established in the United States yet. However, cutaneous leishmaniasis has been seen in our port cities and should always be considered as a possible cause of a chronic ulcer on anyone having worked or lived recently in an endemic area.

The cutaneous lesion of leishmaniasis begins as a pruritic papule that grows and breaks down centrally. The ulcer is painless unless secondarily infected. Although the ulcer may attain a size of 5 to 6 cm. across, it usually heals spontaneously within a year leaving an unsightly scar.

The diagnosis of cutaneous leishmaniasis rests upon the discovery of Leishman-Donovan bodies in biopsies or smears of the local lesion.

The treatment of a single or a few simultaneous ulcers consists of curettage, freezing with carbon-dioxide snow or the local infiltration of a 1 per cent solution of berberine sulfate. Fuadin and Neostibosan (pentavalent antimonials) are reserved for the patient having multiple ulcers.

Verminotic Ulcers. Only two worm infestations are attended by cutaneous ulcerations: dracunculiasis and creeping eruption. *Dracunculus medinensis* (guinea worm) ulcers occur predominantly about the ankles and legs and are found wherever the proper *Cyclops* vector exists but especially in India and Africa. About 50 million people are infested. The female worm, about 1 yard in length and 2 to 3 mm. in diameter, lives beneath the skin of the foot and leg and burrows a hole through the skin to lay eggs. The ulcer begins with burning and itching and a vesicle which, upon becoming secondarily infected, ulcerates and persists.

The diagnosis may be attained by x-ray when the worms are calcified or the sinus is injected with a water-miscible radiopaque medium. The discovery of the typical larvae in the milky fluid that exudes from the ulcer after the application of a warm, wet dressing also establishes the diagnosis.

Antibiotics for the control of secondary infection and the slow winding of the worm upon a small, split piece of wood over a period of a fortnight constitute the safest therapy. Surgical excision of the worm is fraught with the danger of fulminant infection of the wound.

The ulcers that occasionally attend the cutaneous infestation with *Ancylostoma braziliense* (larvae of the dog and cat hookworms) are factitious in origin. The intense pruritis prompts destructive scratching by some sufferers.

The observation of telltale "worm tracks" in the skin and scratch marks about shallow ulcers should prompt immediate suspicion of the cause.

Killing the worms in the skin with an ethyl chloride spray or carbon-dioxide snow stops the trouble.

Vascular Ulcers. Vascular ulcers, with but few exceptions, are limited to the lower extremities. The most important vascular diseases that lead to their genesis are: 1. occlusions of major arteries by emboli, thrombi (arteriosclerosis), and endarteritis obliterans; 2. abnormalities of the veins (stasis ulceration), and 3. hemangiomata.

ARTERIAL OBSTRUCTIVE ULCERS. Although the predominant locations of ulcers relatable to the obstruction of major arteries are the toes and heel, they do occur about the malleoli and over the tibia up to the middle of the leg (Fig. 5). They are usually generated by such injuries as those caused by the rubbing of a bony prominence by a new shoe, the stubbing of a toe, the cutting of a corn or an ingrown toenail, or a bump to the shin. The injury is soon followed by a blister under which the skin dies and within three to five days turns into a dry, black eschar. The eschar separates slowly and after the passage of two to four weeks comes off leaving an indolent, painful, avascular ulcer that does not heal.

The arterial occlusive ulcer is often mistaken for a varicose or stasis ulcer especially when it is located about or above the malleoli and the person has visible varicose veins. Actually, varicose veins are to be found in about 20 per cent of elderly people having arterial disease; consequently, the nonetiologic or randomly unrelated association of varicose veins and arterial occlusive ulceration occurs rather frequently.

The diagnosis of arterial occlusive ulceration rests upon the demonstration of an ar-

ulcer, and a trial of the efficacy of the treatment with bismuth, arsenicals, and penicillin should be undertaken after ascertaining by biopsy that the ulcer is not neoplastic. Leutic ulcers usually heal very rapidly with the above treatment.

The rare indolent lesion of late progressive, nodular, cutaneous, syphilitic dermatitis may be mistaken for cutaneous blastomycosis because healing takes place in the center as the lesion spreads. However, late nodular, cutaneous syphilis has a characteristic raised serpiginous margin that does not contain the characteristic pustules or blastomyces, and consequently cutaneous blastomycosis and late nodular syphilis are readily differentiated.

Another spirochetal disease confined to the tropics that is attended by cutaneous ulceration is yaws (*Treponema pertenue*). The primary lesion of this disease is an ulcer that heals slowly, usually occurring on the legs; the so-called mother yaw. The ulcers of yaws may appear upon the soles of the feet (crab yaws), and when they do they are painful.

Rare causes of chronic cutaneous ulcers are: glanders, anthrax, staphylococci, chromoblastomycosis, and maduromycosis (see Table 1).

TABLE 1. Rare Organismal Ulcers

Disease and Organism	Development of Ulcer	Attendant Phenomena	Diagnosis	Treatment	Occupational Predilection and Predominant Location
Anthrax (malignant pustule) *B. anthracis*	Papule, vesicles, pustule, shallow ulcer with black central eschar	Wide edematous pruritic periulcerous zone, painless ulcer, moderate regional lymphadenitis	Culture and separation from nonpathogenic relatives such as *B. subtilis* by injection into mice	Penicillin	Raw-hide handlers, slaughter house workers, animal-hair handlers Hands, wrists, arms, rarely legs
Glanders (acute) Farcy (chronic) *Malleomyces mallei*	1. Acute form. chills, fever, severe illness, nodule at point of entry breaks down leaving painful ulcer 2. Chronic form: exacerbations and remissions of crops of painful ulcers and abscesses over the whole body	Miliary nodules forming abscesses and ulcers along main lymphatics draining the primary lesion, regional lymphadenitis	Biopsy, culture, serologic tests, skin tests, animal inoculation	Sulfadiazine; (penicillin and streptomycin are ineffective)	Handlers of horses, donkeys, mules Veterinarians Hands and arms
Chromoblastomycosis *Phialophora verrucosa* *Hormodendrum pedrosoi* *Hormodendrum compactum*	Slowly growing papule, warty ulcer, no constitutional symptoms unless secondarily infected	Nodular regional lymphangitis, elephantiasis, large cauliflowerlike masses about the ulcers	Mycologic identification from tissue scrapings and biopsy, culture on Sabouraud's medium	Excision; (effective drug therapy has not been developed yet)	Leg
Maduromycosis (madura foot) Variety of fungi, predominantly *Monosporium apiospermum* and nocardia	Nodules, small abscesses, swelling, small ulcers after rupture of abscesses	Sinuses, progressive enlargement of the afflicted member Painless	Biopsy, Gram's stain and mycologic identification	Excision of cutaneous lesions when unaccompanied by deep penetration Amputation	Foot and hand
Chronic staphylococcal ulcer (resembles botryomycosis of cattle)	Abscess ruptures or is drained and does not heal	None	Culture	Antibiotic to which the organism is not resistant	Legs, arms, buttocks, neck

are related to the stasis of blood in the part must also be viewed with suspicion, because the oxygen saturation of the blood in the veins draining a stasis ulcer is at least as high and often higher than that of the blood in the veins of the unafflicted limb. In short, we do not know the precise cause of the so-called varicose or stasis ulcer. However, recently, while excising chronic stasis ulcers in order to place skin grafts upon normal tissue to cure these ulcers, a number of interesting observations were made: 1. the superficial cutaneous lymphatics are noninjectable in the skin, often far removed from the ulcer; 2. the veins about and beneath the ulcer are abnormal in that they frequently contain thrombi and are extremely friable; and 3. bleeding from the skin is much more intense about the ulcer than it is 2 or 3 inches from it. The significance of these observations is unknown.

The establishment of a diagnosis of stasis ulceration requires that other causes of ulcers of the legs such as arterial occlusion, hematogenic disturbances, trauma, and specific infections be ruled out (2, 3). *The discovery of varices in the extremity bearing an ulcer does not establish an etiologic relationship between the ulcer and venous disease.* Stasis ulcers may be aggravated by arterial obstruction (Fig. 6).

The treatment of stasis ulcers cannot be stereotyped. The acute and subacute stasis ulcers without fibrosis in the base and beneath the skin of the margin, and without atrophy and deep pigmentation of the surrounding skin, usually heal very quickly after the stripping or excision of the varices of the leg and thigh. Before undertaking the stripping or excision of the veins one must make certain that there are no hemolytic streptococci or coagulase-positive staphylococci in the ulcer and that any erysipelatous inflammation that may have existed about the ulcer has disappeared. The clearance of periulcerous inflammation and dangerous organisms from the ulcer before removal of the varices usually can be effected quickly by cleansing the foot and leg with soap and water twice daily. Elevation of the leg if it is edematous is also helpful. Frequent changing of saline-wet compresses applied to the ulcer itself, and parenteral administration of an appropriate antibiotic, proven effective by sensitivity tests, should be employed. The application of antibiotics and digestives to the ulcer itself has not been proven to be more effective in securing bacterial cleanliness of the ulcer than simple cleansing with soap and water and the frequent changing of saline-wet compresses.

After the excision or stripping. elastic bandages or stocking supports should be worn until the ulcer is healed and the foot, ankle, or leg does not swell appreciably with walking, standing, or sitting. In addition, the feet

TABLE 2. Treatment of Chronic Stasis Ulcers

	Treatment				
	A	B	C	D	E
Number Treated	44	6	12	34	48
Number Free of Ulcer for 2 Years	4	1	6	11	37
Number with Recurrent Ulcer	40	5	6	23	11
Per cent Success (2 years)	9	16	50	32	77

Treatment A: Ligation, stripping, and excision of varices. Wearing elastic supports.

Treatment B: Ligation, stripping, and excision of varices. Wearing elastic supports and ligation and division of external femoral or popliteal vein.

Treatment C: Ligation, stripping, and excision of varices. Wearing elastic supports, ligation and division of femoral or popliteal vein, excision of the ulcer with a narrow margin of skin, and immediate skin grafting.

Treatment D: As for C, excepting that the femoral or popliteal vein was not ligated and divided.

Treatment E: Ligation, stripping, and excision of varices. Wearing elastic supports. Excision of the ulcer and all abnormal skin about it and immediate skin grafting.

$X^2 (C - D) = 1.18, P = > .2, < .3$
$X^2 (D - E) = 16.4, P = < .001$
$X^2 (C - E) = 3.5, P = > .05, < 0.1$

Fig. 5. Ulcer of the leg due to arterial (arteriolar) deficiency. Ulceration at this point had appeared, healed, and recurred at intervals for 10 years and had been present for one year at the time the above photograph was taken. The patient was a woman, aged 34 years. *Practically all the charcteristics of ulcer due to arteriolar disease as described in the text were present in this patient. Healing was finally* achieved by rest, heat, cleanliness, and application of a pressure bandage to the leg.

terial occlusion by oscillometric testing and femoral arterial arteriography. The diagnosis cannot be made with certainty by the exercise of ordinary diagnostic maneuvers such as the failure to feel pulses in the peripheral arteries, the testing for rate of capillary filling, the observation of the rate of growth of nails, and the distribution of hair. Neither can it be made on the basis of complaints that may be typical of intermittent claudication. In other words, one cannot assume that an ulcer is not related to arterial occlusion because varicose veins are visible; and, conversely, one cannot assume that an ulcer has an arterial occlusive basis from nonmensurable clinical observation; arteriography and oscillometry often are required to establish the etiology of a vascular ulcer.

The treatment of an arterial occlusive ulcer depends upon the location and extent of the occlusion. Removal of the obstruction by thrombectomy, endarterectomy, or the placement of a graft should be practiced whenever possible. In case the occlusion is too extensive or involves the divisions of the popliteal artery, making surgical correction impossible or its attempt excessively hazardous, the treatment must be directed toward the control of infection with antibiotics and meticulous cleanliness and the prevention of progressive thrombosis by the administration of heparin (100 to 150 mg. daily). Should clean granulation tissue appear and cover the base of the ulcer, a thin split-thickness graft will often take upon it and cure the ulcer for a time. However, unless the arterial occlusion can be removed or circumvented by an operation, the probability that an arterial occlusive ulcer will heal is less than 0.5. Often in such cases the ulcer enlarges, and gangrene of the toes and foot occurs, necessitating an amputation.

The treatment of an arterial occlusive ulcer as a chronic stasis or varicose ulcer is an inexcusable mistake.

THE STASIS ULCER. The stasis ulcer or varicose ulcer is likely misnamed. For many years, the theory of *blood reflux* through varicose veins was accepted as an adequate explanation for the genesis of stasis ulcers. However, recent measurements of the direction and speed of blood flow in varices have demonstrated that reflux or reverse flow is only an evanescent phenomenon and that blood flows upward at normal rates in varices after the individual stands awhile. The idea that the ulcers associated with varicose veins

Fig. 7. Extensive stasis ulceration and fibrosis. Left, Mr. G. W., aged 54, chronic stasis ulcer for 33 years beginning after thrombophlebitis of the left leg. The ulcer is circumferential and includes the dorsum of the elephantiasic foot. Amputation recommended to him but refused. Right, same foot and leg a year after completion of Treatment E of Table 2. Only a 1 cm. ulcer exists over the instep. This arose after he abraded it on a stirrup while riding wearing oxford shoes. This result is classified as a therapeutic failure in Table 2, Treatment E.

and legs must be washed daily. Nothing is more conducive to the recurrence of an acute stasis ulcer than a filthy foot and leg!

The treatment of a stasis ulcer having an avascular fibrotic base, fibrosis beneath the skin surrounding the ulcer, deep pigmentation or atrophy of the periulcerous skin, and lack of injectable superficial cutaneous lymphatics is another matter. A stasis ulcer having the above characteristics may be called chronic. Chronic stasis ulcers are usually found upon the legs of persons who have had thrombophlebitis in the deep veins (4, 5) or varices, or have had their common femoral veins ligated. The results of five methods of treating the chronic stasis ulcer are shown in Table 2.

The extent of the excisions practiced in the Treatment Forms C, D and E (p. 143) are shown in Figure 7.

Before undertaking the stripping, excision, and ligation of varices above and about the chronic ulcer and the wide excision of the ulcer itself, the same preoperative precautions and measures taken for the acute stasis ulcer must also be exercised.

The technical factors found to be important in the conduct of Treatment E are listed in Table 3.

TABLE 3. Technical Factors Important in Treatment E of Table 2.

1. Hemostasis with triple 0 chromicized catgut.*
2. Excision of the entire fibrotic base of the ulcer and surrounding inelastic or atrophic skin and in underlying subcutaneous fascia taking care to leave periosteum and peritendineum.
3. Immediate coverage of the entire defect with a thick partial-thickness autograft of skin.
4. Feet and legs kept upon the bed for 14 to 21 days.**
5. Wear elastic supports indefinitely.

* Nonabsorbable hemostatic sutures are prone to come through the graft even years after primary healing and recurrent ulceration is prone to occur at their points of egress.

** To permit the patient to hang the legs over the edge of the bed, to sit in a chair, or to walk before the fourteenth to seventeenth day is often followed by more or less confluent petechial hemorrhages beneath the graft with delayed dissolution of the graft that was "completely taken" on the eighth or tenth postoperative day.

What can be accomplished by applying the principles of Treatment E is illustrated in Figure 7.

Fig. 6. Stasis ulcer. Top, Mr. B., aged 69, had a chronic stasis ulcer for 20 years. The ulcer shown had not healed for five years. The dorsalis pedis, posterior tibial, and popliteal pulses were normal. The skin about the entire ankle was underlain by scar, depigmented, and atrophic. The extent of the cutaneous excision practiced in Treatment Forms C and D of Table 2 is outlined by the continuous inked line. Middle, a medial view taken during the operation before graft emplacement; bottom, a lateral view taken four weeks postoperatively. The middle and bottom pictures show the extent of the excision practiced upon this patient illustrating Treatment E, Table 2.

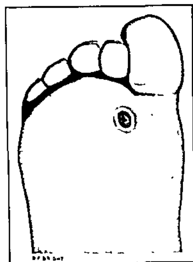

Fig. 8. Perforating ulcer of the sole of the foot in a man 70 years old. Such ulcers are deep and are frequently associated with a large amount of callus. They may occur in patients with arterial as well as with neurogenic lesions such as tabes dorsalis and diabetic neuropathy.

sociated with chronic perforating ulcers overlying the heads of the metatarsals, especially of the first, third, and fifth (Ch. 19, Fig. 4). These ulcers are called malperforant. They frequently constitute the site of origin of phlegmonous and other necrotizing infections of the plantar space and chronic septic arthritis of the metatarsal phalangeal joints followed inevitably by gangrene of the toes. For these reasons, the malperforant requires vigorous treatment. Before deep infection of a joint or plantar space occurs, the proper fitting of a metatarsal bar and daily careful washing of the foot, after securing healing of the ulcer by rest in bed and the careful removal of the surrounding callus, will prevent further trouble. In case the malperforant has extended into a joint as determined by gentle probing of its depths and x-rays, the only effective treatment is the resection of the joint and amputation of the attached phalanges.

Hematogenous Ulcers. Chronic ulcers of the lower extremity are occasionally associated with diseases of the blood such as chronic anemia (thalassemia minor, sickle cell anemia, and aplastic anemia), polycythemia, chronic thrombocytopenia, leukemia, and cryoglobulinemia. The hematogenic ulcers have no distinguishing characteristics and are often mistaken for stasis ulcers. The differentiation of the hematogenic ulcer of the lower extremity from the stasis, bacterial, fungal, and arterial flow deficiency ulcers rests upon clinical suspicion, the examination of the blood, and response to specific therapy.

A chronic ulcer upon the lower extremity of an anemic or thrombocytopenic person requires that specific examinations of the blood be performed to determine the cause of the anemia and thrombocytopenia, and that the hemic abnormality be overcome by appropriate treatment before undertaking surgical correction of the ulcer. To attempt the excision and grafting of hematogenic ulcers, or the excision or stripping of varices that may randomly attend them, before the anemia or thrombocytopenia is treated, only invites a recurrent ulceration that is often larger than it was before the surgical correction was attempted.

The chronic ulcer upon the lower extremity of a person having chronic leukemia or Hodgkin's disease is often peculiarly painful and difficult to treat. Even after restoration of the red blood cell volume to normal with transfusions and control of an excessively high white cell number, the ulcers fail to heal. In such cases, the application of thin split-thickness skin grafts to clean granulating surfaces cleared of hemolytic streptococci and coagulase-positive staphylococci, sometimes secures epithelial coverage. Before undertaking the grafting of an ulcer on a leukemic person, a search for cryoglobulins should be made, and a biopsy of the edge of the ulcer should be performed in order to rule out the remote possibility of the existence of leukemia cutis as its cause.

The rare chronic ulcer of the lower extremity associated with cryoglobulinemia mimics the stasis ulcer. However, the possibility that cryoglobulinemia might be the cause of the ulcer is usually suggested by the coexistence of Raynaud's phenomenon in the hands and the occurrence of the ulcer after exposure to cold. The rapid healing of the ulcer while the person is kept in a warm environment and the demonstration of cryoglobulins by electrophoresis practically clinch the diagnosis. However, the discovery of cryoglobulinemia should prompt an immediate search for leukemia, Hodgkin's disease, multiple myeloma, and the collagen diseases

Angiomatous Ulcers. A peculiar form of stasis ulcer is that which appears about the ankles of adolescents and young adults having angiomatous anomalies of the arteriovenous systems of the legs and thighs. Some of them have visible, diffuse, cutaneous, and cavernous hemangiomata; others do not. However, the bones of the afflicted part grow more rapidly than those of the opposite, normal limb, producing unilateral localized gigantism. Such cutaneous ulceration cannot be successfully treated unless the angioma is removable, and this is rarely feasible except by amputating that part of the limb containing the angioma. The removal of varices and the ligation of arteries to the afflicted part of the limb provide, at best, only brief respites from the progressive ulceration. Irradiation therapy is ineffective.

VASOSPASTIC ULCERS. Vasospasm is a very rare cause of chronic ulceration. Raynaud's disease is occasionally accompanied by *small* (less than 1 cm. diameter) ulcers of the pads of the finger tips. However, most of the chronic ulcers of the finger tips are manifestations of organic arterial occlusions relatable to cervical ribs, axillary crutch injury ("crutch paralysis"), thrombotic arteriosclerotic, and traumatic blocks of the subclavian, axillary, or brachial arteries, and occlusions of the digital and other arteries of the hand by thromboangiitis obliterans and pneumatic-hammer injuries. In addition, collagen disease (dermatomyositis, periarteritis nodosa, and scleroderma, especially the local form acroscleroderma), is a relatively frequent cause of chronic digital ulcers. All the various types of organic arterial occlusions of the vessels of the arm and hand, as well as the collagen diseases, crutch injuries, Buerger's disease, and pneumatic-hammer injuries, may be associated with blanching or blueing, pain with exposure of the hand to cold, and the reactive cyanotic hyperemia following warming that once was thought to be characteristic only of Raynaud's disease. Obviously, the ascription of a chronic ulcer of the finger pads to Raynaud's disease requires more evidence than the observation of the typical Raynaud's responses to cold and warming. It requires biopsy of a muscle, of the skin of the digit, or of a visible lesion at some distance from the ulcer to rule out collagen disease (especially scleroderma), x-rays of the cervical spine to rule out cervical ribs, and arteriographic examination of the arteries of the arm and hand to rule out the arterial occlusive diseases.

Obviously, the treatment of the chronic ulcer of the finger tips varies with the cause of the ulcer and includes such varied maneuvers as thrombectomy or reconstitution of the flow through or about a localized obstruction of a major artery, the resection of cervical ribs or the anterior scalene muscle, the proper selection of a crutch ("crutch paralysis"), change of occupation (pneumatic-hammer disease), endocrine and other therapy of collagen disease, and *rarely* sympathectomy (Raynaud's disease).

For a time, cervicodorsal sympathectomy was considered to be the appropriate treatment for chronic ulceration of the finger tips when Raynaud's phenomenon could be elicited. However, because under these circumstances sympathectomy has not proved to be an effective means of securing more than a temporary, though at times a prolonged, relief of pain and ulcer, it has been largely abandoned as a primary therapeutic maneuver for digital ulcers associated with Raynaud's phenomenon, excepting for the treatment of the rare chronic ulcer associated with Raynaud's disease itself. However, cervical and upper dorsal sympathectomy is still indicated in the treatment of chronic ulceration of the hand associated with Raynaud's phenomenon, whenever the more specific therapeutic measures fitting the cause of the phenomenon have failed even though, at best, only temporary relief is to be expected from the sympathectomy.

Neurogenic Ulcers. A few chronic ulcers of the finger tips and plantar surfaces of the feet have neurogenic origins (Fig. 8). Syringomyelia, by virtue of the enervation of pain and temperature sensation to the hand, permits repetitive thermal injury to the fingers by cigarettes and burning matches, thereby facilitating the genesis of small, chronic, painless, traumatic ulcers of the skin of the fingers. The proper neurologic examination makes the diagnosis.

Diabetic neuropathy, which early affects loss of pain (pin-prick and inflammatory) and temperature discrimination of the toes and plantar surface of the foot, is often as-

Fig. 9. Squamous cell carcinoma (Marjolin ulcer) of the thigh and buttock. The patient had an old ulcer produced by a burn 13 years previously, which failed to heal. The hyperplastic changes at the edge of the ulcer were of recent origin, however. (Courtesy Dr. J. W. Gale.)

Decubital Ulcers. Any poorly nourished patient suffering from such a prolonged and debilitating illness as chronic intestinal obstruction or tuberculosis may develop decubital ulcers or bed sores, unless the malnutrition is corrected and adequate nursing care is exercised in turning the patient and protecting bony prominences. Local circulatory impairment, due to pressure, plays an important role in the etiology of the decubital ulcers. The skin over the sacrum, iliac crest, trochanter, external malleolus, and heel is especially susceptible on account of the continuous pressure sustained at these points against the underlying bone (Fig. 10). Patients with nerve lesions (spinal cord injury, tabes, and the like) are more susceptible to decubital ulcers than others. The skin becomes slightly reddened, a blister forms, and shortly thereafter the tissue becomes indurated and the skin acquires a cyanotic tint. By this time, however, it is too late to prevent the formation of the ulcer. The process of separation of necrotic tissue from living tissue may extend over a surprisingly long period of time (two to four weeks) and when completed may reveal an enormous destruction of tissue, sometimes exposing the bone. Repair and filling in with granulation tissue is even a slower process. *Occasionally, in neglected cases, an in*fection spreads into the adjacent tissue. The added burden of the infection on an old or debilitated patient may be sufficient to cause his death. The development of decubital ulcers is a reflection on the physician and, to a lesser extent, on the nursing care. If proper attention is paid to the patient's nutrition by maintaining a good food intake with a sufficient protein content and adequate nursing care, i.e., frequent turning and light massage, they will be uncommon. Such treatment is likewise important in therapy of the ulcer, once it has developed. Attention should be directed to cleanliness, bland dressings, and elimination of pressure over the ulcer; healing, however, is slow and requires weeks. Successful closure of the defect by plastic procedures including skin graft (e.g., sliding pedicle graft) can be accomplished after at least partial correction of the nutritional deficits.

Ulcers Due to Radium and X-ray. Shortly after the introduction of radium and x-ray in the treatment of malignant tumors, ulcerations resulting from excessive radiation were commonly encountered. Fortunately, how-

TABLE 4. Rare Vascular Ulcers

Name	Pathogenesis, Predominant Location of the Ulcer, and its Characteristics	Diagnosis	Treatment	Reference
Hypertensive ischemic ulcers	Local cutaneous arteriolar occlusions. Lateral and posterolateral surfaces of the leg. Covered by an avascular membrane with an ischemic border	Biopsy	Cleanliness. Antibiotics. Bed rest until healing begins. Thin split-thickness skin grafting	Hines, E. A., Jr., and Farber, E. M. Proc. Central Soc. Clin. Research, 19:15–16, 1946
Chronic pernio ("erythrocyanosis," "lupus pernio," "chronic chilblains")	Exposure to cold. Located about the ankle and around the leg, predominantly in young women. Spotty erythema, blister, ulcer with a purple base	Biopsy to rule out erythema induratum (no tubercles)	Fever therapy (typhoid vaccine) for active ulceration. Keep out of the cold	McGovern, T., and Wright, I. S. Am. Heart J., 22:583–605, 1941
Erythema induratum	Cutaneous and subcutaneous nodules which break down and become chronic ulcers of the mid leg (calf and shin) of middle-aged women and men. Disease resembles chronic pernio	Biopsy—cutaneous tubercles (no tubercle bacilli in the lesion)	Systemic antituberculous therapy. Excision and skin grafting for the nonhealing chronic ulcer	Montgomery, H. O'Leary, P. A., and Barker, N. W. J.A.M.A., 128:335–341, 1945
Livedo reticularis	Diffuse cutaneous arteriolar obstructions. Reticular (netlike) lividness of the feet and legs (occasionally hands and arms), chronic ulceration about the ankles	Appearance of the extremity	Sympathectomy and avoidance of cold and fatigue	Williams, C. M., and Goodman, H. J.A.M.A., 85:955–958, 1925
Ergotism	Distal arterial thrombosis. Gangrene of tips of toes and rarely of fingers followed by slough of the gangrenous skin leaving a slowly healing ulcer (History of taking ergot preparations for migraine or abortion or abnormal menstrual bleeding)	History	Removal of the drug. Local amputation if spontaneous healing does not occur	
Frostbite	Distal arterial occlusions. Hemorrhagic blisters overlying dead skin which sloughs leaving an ulcer that heals rapidly if small	History and appearance of the acute lesion	Split-thickness skin grafts directly upon granulation tissue	
Traumatic arteriovenous fistula	Ulcer of the stasis type. Penetrating injury to leg or arm Followed by swelling and warmth of the leg and the growth of varices	Auscultation over arteries of the affected member, angiography	Repair of the fistula	

because idiopathic cryoglobulinemia is rare and the secondary form is not. There is no specific treatment for the cryoglobulinemic ulcer. Skin grafts take readily on the clean, granulating base of the ulcer. Other rare vascular ulcers are listed in Table 4.

Neoplastic Ulcers. Practically all malignant neoplasms located in and immediately beneath the skin, whether primary (squamous cell carcinoma, basal cell carcinoma, sweat gland cancers, melanomas) or metastatic, will break down at times, producing chronic, progressively enlarging ulcers.

Marjolin's ulcer is a peculiarly slowly growing carcinoma of the skin, having a scar as its locus. Burn scars constitute its most common site of origin (Fig. 9).

Biopsy, of course, is requisite for the diagnosis of a neoplastic ulcer. The treatment of a neoplastic ulcer is ablation of the primary lesion and its regional lymphatic drainage if nodal enlargement exists.

of gangrene, owing to the lack of muscle in such structures as the phalanges and skin and the interference with voluntary muscular contractility attendant upon pain that is associated with such nongangrenous processes as thrombophlebitis, ruptured tendons and ligaments, and fractures. In other words, the loss of all modalities of cutaneous sensation is the most dependable manifestation of early gangrene.

All gangrenous processes are associated with some discomfort or pain. The severity varies a great deal, being scarcely noticeable by the diabetic neuropath with a gangrenous foot, and being excruciating with clostridial cellulitis and myositis and with acute occlusions of the abdominal aorta (saddle emboli).

All forms of gangrene, infected or not, are accompanied by the general signs of tissue death—namely, fever, leukocytosis, and illness. *Dry gangrene* occurs when the death of tissue is due to arterial obstruction without an associated venous obstruction or infection. *Moist gangrene* develops if the gangrenous process begins when the tissue is edematous and filled with fluid, or in the presence of infection or venous obstruction. Gangrene primarily affects the extremities, being much more common in the lower than upper. Often, indeed, amputation is necessary to save the patient's life. The details of amputations will be found in Chapter 18. Silbert and Haimowici (6) have aptly summarized the needs for amputation in ischemic gangrene to be dependent upon "the extent of gangrene or ulceration, degree of infection, condition of adjacent areas, degree of arterial impairment, and severity of pain." Conservative amputations are being advocated more and more because antibiotics are making them safer.

Arteriosclerotic Gangrene (Senile Gangrene). When gangrene results from arterial obstruction due to arteriosclerosis obliterans it is practically always of the dry type. It is relatively common and occurs in the aged as a result of narrowing of the lumen by the sclerotic process and may or may not be associated with an accompanying thrombosis of the artery. The development of gangrene is usually preceded by a history of pain in the extremity which is, in most instances, located in the calf of the leg. This pain may have been present for years, is dependent upon a decreased blood supply, and is most easily precipitated by extended exercise of the extremity such as walking (*intermittent claudication*). The feet become cold very readily and a feeling of numbness is usually complained of. The actual gangrenous process may occur spontaneously or be started by a slight injury which precipitates inflammation, thereby aggravating the effects of the vascular occlusion. Several toes or the entire foot may be included in the process. Before the line of demarcation forms, a moderate amount of burning pain is complained of. It is frequently relieved by elevation of the foot, especially after the line of demarcation is formed. There is usually a definite sequence of events as far as color reaction is concerned in the development of the gangrene. The tissue first becomes pale and white, and after varying periods of time turns red, later cyanotic, and finally black.

Examination reveals the dried, shriveled, and mummified characteristics of dry gangrene with a hyperemic zone intervening between it and normal appearing skin. Elevation of the foot causes a blanching of the hyperemic areas regardless of whether or not a gangrene is present. There will be no pulsation of the arteries below the obstruction. At times, the entire artery from the femoral on down is involved so that even the pulsation of the femoral artery in the groin may be decreased or even absent. A roentgenogram will reveal calcification along the course of the artery, a finding, however, which is often noted in arteriosclerotic patients without circulatory disturbance. Fever is absent except on the occasions when the gangrenous area is extensive or associated with an infection. Since the gangrene is usually dry, the offensive odor of putrefaction is absent. The line of demarcation will usually not form until the gangrenous process has been present for ten to fourteen days. At first there is no break in the continuity of the skin, but a crack soon appears, deepens, and if the patient refuses operative treatment and survives, will result in a spontaneous amputation.

TREATMENT. In general, the treatment of arteriosclerotic gangrene is amputation, at a level far above the line of demarcation, in tissue whose blood supply is not appreciably diminished (Fig. 11). A more conservative

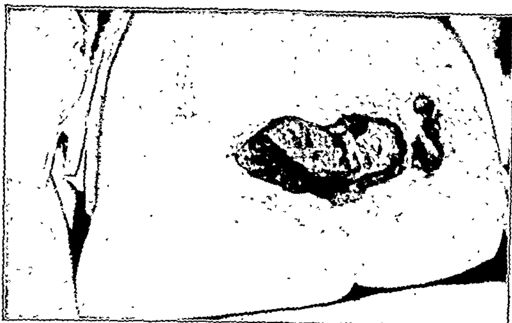

Fig. 10. Decubital ulcer. This ulcer is in the sacral region of a patient with paralysis and anesthesia due to spinal cord injury and was produced by the pressure of a plaster cast applied for fixation of the fractured spine. Healing was eventually complete.

ever, because of a better understanding of dosage and other factors, these ulcers are decreasing in number. The first evidence of injury is a hyperemia of the skin, which is the seat of most of the damage, because of the greater dose of radiation it receives, but more especially because of the sensitiveness of the skin to the rays. The ulceration does not occur for some time after the burn (one to four weeks) and is, in reality, preceded by gangrene. The base is usually smooth and red. The skin surrounding the ulcer is hyperemic and pigmented. Considerable pain may be present. Healing takes place unusually slowly and the ulcer may be unchanged for years. Excision of the ulcer with application of a skin graft may result in a cure. Occasionally a squamous cell carcinoma develops at the site of such a burn. This type of carcinoma is usually not very rapidly invasive and responds satisfactorily to thorough excision.

GANGRENE

The recognition of gangrene is simple after the skin turns black and the member exudes a fetid charnel odor. However, when these signs appear nothing can be done to save the part. Consequently, early recognition of impending gangrene and determination of its cause, while something might be done to limit or reverse the process, are very important. The cardinal signs of impending or early gangrene are: 1. total peripheral sensory denervation manifested by numbness, and total hypesthesia or anesthesia; 2. poikilothermism; and 3. muscular weakness or paralysis. Of these three the neurologic signs are the most dependable, provided that the examination is conducted carefully and intelligently, and such injury as transection of the spinal cord or large nerves does not exist. For instance, diabetic neuropathy without gangrene often is associated with hypohidrosis, anesthesia to pin prick, lack of temperature sense, lack of vibratory sense, and absence of tendon jerks in the foot and lower leg. However, tactile sense and muscle power are not lost with diabetic neuropathy while they are lost early with gangrene.

Poikilothermism is often misleading; with ambient temperatures below 26° C. it often attends acute thrombophlebitis, emotional disturbances, and arterial surgery when there is no danger of gangrene. And when the ambient temperature is above 34° C., the skin of the early anhidrotic gangrenous toe, foot, or leg may feel warmer than the evaporatively cooled, normal sweating extremity.

The assessment of muscle contractility is also often of little use in the early detection

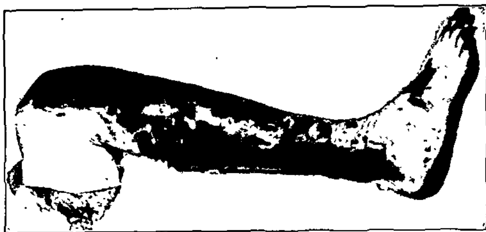

Fig. 12. Gangrene of foot and leg resulting from embolus to the femoral artery, in a young man, aged 26, with rheumatic heart disease.

the vessel wall caused presumably by thrombosis with subsequent canalization or by a primary thickening of the wall of the blood vessel from an inflammatory reaction of some kind. The feet are involved more often than the hands, but there is a tendency toward chronicity with involvement of first one extremity then another. Ulcers of the toes are commonly present and are associated with redness, cyanosis, and mild edema. The disease is described in detail in Chapter 25.

Gangrene Due to Embolism and Thrombosis. The gangrene produced by an embolus is often spectacular because of the suddenness and severity of the initial symptoms. The size of the clot is, no doubt, in most instances increased by an associated thrombosis extending back to the first major branch. The production of the embolus is dependent upon the presence of a primary site, i.e., endocarditis (Fig. 12), pneumonia, typhoid fever, septicemia, and so forth. The embolus may arise from a heart valve, the wall of the heart, the auricular appendage, or the lung. Obviously, superficial gangrene will be produced only when the embolus lodges in one of the four extremities; the legs are more commonly involved than the arms. Frequently the patient is not aware of the primary lesion responsible for the embolus. The femoral artery is the most common site of embolism; next in order of frequency is the common iliac artery, the brachial artery, the aorta, and the popliteal artery (Pearse). Gangrene of both lower extremities may occur when the aorta is occluded, except when a partial obstruction of the distal portion of the abdominal aorta has been produced by such a lesion as an aneurysm, for a period sufficiently long to allow collaterals to develop. The incidence of gangrene following ligation of smaller vessels is approximately as follows: common iliac (45 per cent), popliteal (15 per cent), common femoral (15 per cent), and femoral below profunda (8 per cent). Gangrene is relatively uncommon (somewhat less than 10 per cent) when the major arteries of the upper extremity are occluded, occurring with about equal frequency in obstruction of the axillary and subclavian arteries, but is decreased to near zero when ligation is done between the thyrocervical trunk and the circumflex humeri arteries. In general, gangrene is much more frequent in embolism of the lower than in the upper extremities.

The first symptom experienced is usually a sudden severe pain in the extremity (commonly the calf of the leg), associated with a complete disability including paralysis. The foot becomes white and cold and the muscles spastic. If the embolus has lodged at the bifurcation of the aorta, both legs will usually be involved. After several hours the white, pallid color changes to a cyanotic blush and, after 24 to 48 hours, gangrenous patches will develop.

If the patient is seen within a few hours after the embolus has lodged in the artery, the clot should be removed (embolectomy). If this is done early and completely, gangrene

Fig. 11. Arteriosclerotic gangrene. Amputation was advised, but the patient, a woman aged 67 years, refused and left the hospital.

attitude may be adopted in certain circumstances; for example, when gangrene is limited to one or two toes and popliteal pulsation is still present, a transmetatarsal amputation may be sufficient (McKittrick 7). However, if at any time during hospitalization the *gangrenous process should spread upward or* to other toes, a high amputation in the lower third of the thigh (or rarely in the upper third of the leg) should be performed without further delay. The choice of level for amputation is determined by various tests, including the histamine flare test, as described in Chapter 18. *As already stated, an amputation is not* urgent while the gangrene is of the dry type, but if infection develops, giving rise to the so-called wet type of gangrene, immediate amputation will be indicated. During the preoperative period the foot is protected with a cradle without electric bulbs, since heat is *detrimental* because of increased oxidation in the tissue and other causes, as demonstrated in the experimental work of Brooks and Duncan (8). Strict aseptic care, using sterile towels to protect the involved area against contamination *from such nonsterile objects as* bed clothing, must be exercised at all times.

When amputation is performed in the presence of an infection, it is usually advisable to leave the stump wide open, resorting to reamputation at a later date when the stump is healed or the infection under control. Such serious complications as tetanus, gas bacillus infection, and septicemia are very apt to develop in patients with moist gangrene, particularly following amputation. To combat *these possibilities, it is, therefore, advisable* to use chemotherapy.

Diabetic Gangrene. This type of gangrene is similar to arteriosclerotic gangrene insofar as arteriosclerosis is frequent in diabetics and is the major factor in production of the lesion. However, diabetic gangrene is much more *serious because of the higher incidence* of infection which a diabetic patient is less able to withstand. Once gangrene of a significant degree develops in a diabetic patient, amputation is practically always indicated; delay is rarely *justifiable except for the preoperative* correction of acetonuria. It should be emphasized, however, that uncomplicated infections (as occur most commonly in the foot) can be treated by incision and drainage as in nondiabetic patients. Of recent years amputations are becoming less radical (7). More details *of diabetic gangrene will be found in* Chapter 19.

Thromboangiitis Obliterans (Buerger's Disease). The obstruction in thromboangiitis obliterans is apparently due to a thickening of

Fig. 13. Traumatic gangrene of hand, 22 hours after injury. Note the crushed and lacerated tissues of the forearm; a severely comminuted fracture of the radius and ulna was also present. Amputation necessary because of the rapid progression of the gangrene. (St. Louis City Hospital.)

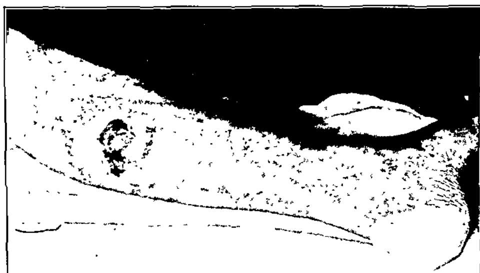

Fig. 14. Hemolytic streptococcus gangrene of Meleney. Onset four days previously, in a healthy man 26 years of age, with swelling of leg, fever, and other systemic manifestation of infection. This is an unusually mild case and subsided spontaneously.

lesion responds well to antibiotics, particularly to heavy doses of penicillin.

Meleney has also described a *synergistic* or *symbiotic type* of bacterial gangrene which on culture yields in most instances a hemolytic *Staphylococcus aureus* and a microaerophilic nonhemolytic *streptococcus*. Because of its tendency to spread, it is often called a phagedenic ulcer. This lesion differs sharply from the one described above in many respects. *It is apt to be a single lesion and* commonly develops about the tenth postoperative day at the site of a stay suture following an abdominal operation. The lesion at first resembles a carbuncle with a wide area of inflammatory tissue and, in reality, produces gangrene of the skin, because of the undermining characteristics of the infection. *The destructive effect is usually superficial* and confined to the subcutaneous tissue immediately under the skin, but spreads rapidly in all directions. As the infection progresses, the skin becomes a bright pink in color for a distance of 1 to 3 cm. from the edge of the ulcer, but after two or three days the margin of this pink area becomes raised, cyanotic, and finally becomes necrotic, leaving an ulcerating base. The edges are extremely

will be prevented. The position of the embolus will be much higher than the external signs, but accurate localization is sometimes difficult, often requiring arteriography. It is usually preferable to open the artery over the upper limits of the clot, which is removed by suction and gentle traction. If the patient is seen after the late signs of gangrene are manifested, embolectomy will be of no value and it will be preferable to wait for the development of a line of demarcation between the gangrenous and viable tissue before performing amputation. Rarely is embolectomy indicated if more than 48 hours have elapsed since the embolism.

Regardless of whether or not embolectomy is performed, certain routine procedures are advisable. The use of vasodilating drugs such as papaverine (0.5 grain) or sodium nitrite (1 grain) is advisable. The extremity (e.g., foot) is protected by a cradle, but no external heat should be applied since heat accelerates oxygen consumption in the affected extremity. The extremity should be kept in a slightly dependent position—not elevated. Regardless of whether or not embolectomy has been performed, the patient should be heparinized immediately and a delayed clotting time maintained for several days (Chapter 25).

Traumatic Gangrene. Because of the increasing number of industrial and automobile accidents, it is becoming necessary that traumatic gangrene be given more consideration than previously, especially when we consider that many amputations performed at the present time for crushed or injured extremities are in reality not necessary. Before the aseptic era, amputations for such injuries were indicated to prevent the universal development of serious infection. Such infection can, at the present time, be largely prevented by proper treatment of the wound (Ch. 13). Although a limb may be severely damaged, it is certainly worthwhile, with a very few exceptions, to postpone amputation with the hope that a sufficient blood supply will develop from the unsevered tissue to prevent gangrene. This is especially true if the bones of the extremity are not fractured. Often it will be discovered that the gangrene will be limited to the toes or fingers and that the important structures, such as the joints, can be preserved. It may require several weeks for collateral circulation to develop to the point where healing will progress, but if a portion of the hand or foot can be saved (even if it is partly disabled), it is usually of more value to the patient than an artificial limb. One of the strongest arguments for conservative treatment is that amputation may be safely performed at a later date, if it becomes evident that the extremity distal to the injury cannot survive. If the patient is watched carefully, only on rare occasions indeed will this delay jeopardize the patient's life, particularly since antibiotics are available for the control of infection. However, if considerable tissue (particularly muscle) is distinctly not viable (Fig. 13), it will be a dangerous focus for the development of gas gangrene. Débridement and primary repair of partially severed extremities should be done with as little manipulation as possible to prevent injury to what blood supply is remaining. It is surprising how often huge amounts of soft tissue which are attached to the body by mere shreds will survive, especially if the patient is received immediately after the accident and the wound properly treated. Frequently, sympathetic block with Novocain, repeated at intervals of a day or two, will be effective in decreasing spasm and increasing blood supply. The massive injuries of war are discussed in Chapter 42.

Bacterial Gangrene. Perhaps the most serious type of gangrene is that produced by a number of gas-producing anaerobic organisms, among which the *Cl. perfringens* (*B. welchii*), *Cl. oedematiens*, and *Cl. septicum* are the most important. It was an extremely common affliction during World War I, but is encountered only occasionally in civil life. For detailed description see Chapter 7.

In 1924, Meleney described a particularly serious type of gangrene caused by the *hemolytic streptococcus*, which is definitely characteristic, and can readily be differentiated from the others. It is now relatively uncommon. The initial lesion may or may not be associated with trauma. The skin over a large area becomes red, slightly swollen, and hot. A moderate amount of pain and tenderness are present. After 24 to 48 hours this area of redness becomes cyanotic, and blisters form on the surface. A short time later the skin becomes definitely gangrenous and separation from the viable tissue begins (Fig. 14). The

Fig. 16. Gangrene due to freezing. A, four days after freezing; B, five days later. Note that definite demarcation is beginning to show up on the left foot. Patient contracted tetanus on the fourteenth day and died. (St. Louis City Hospital.)

almost indistinguishable from that caused by the symbiotic growth of the staphylococcus and streptococcus. Amebas may be found in secretions obtained from the depth of the wound, in tissue removed, or by biopsy. The lesion responds well to antiamebic therapy.

In advanced cases of Raynaud's disease the fingers and toes may develop a gangrene which may or may not be associated with considerable pain. The gangrene, however, is always of a superficial type; never is an entire extremity involved. For detailed discussion see page 146.

Noma is a gangrenous process of infectious origin occurring about the mouth and cheeks of debilitated children, but is fortunately becoming quite rare.

Gangrene resulting from the poisonous effects of ingested *ergot* is extremely rare, but may occur in elderly people who have eaten large quantities of rye bread contaminated with the fungus, *Claviceps purpurea.* Young women who have taken large amounts of ergot to promote abortion may also suffer from the disease. The most frequent sites affected are the fingers and toes.

Gangrene resulting from *strangulation* is, of course, observed commonly in the intestine in strangulated hernias. Rarely it occurs in the gallbladder as a result of edema and thrombosis of vessels. Still more rarely is it encountered in extremities following injuries in which a plaster cast has been applied too tightly. Such an event is obviously a serious reflection on the surgeon responsible for the application of the cast.

Gangrene of the lung is a form of pulmonary infection in which several (probably symbiotic) organisms are involved and is accompanied by foul expectoration and fulminating symptoms.

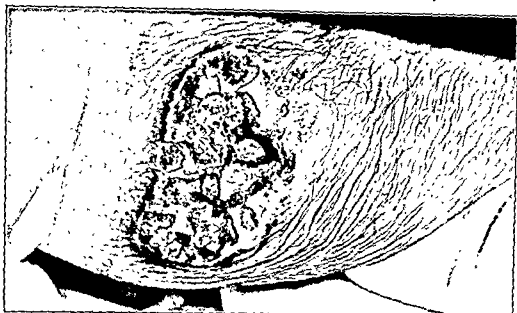

Fig. 15. Bacterial gangrene, symbiotic type (*Meleney*). *Onset six months previously in a woman aged* 30 years. When first seen, the edges of the ulcer were raised, reddened, and very tender; a few patches of gangrenous skin were likewise present. Culture revealed a microaerophilic nonhemolytic streptococcus and a hemolytic staphylococcus. The photograph was taken after seven days' rest *in bed with meticulous* care of the wound. Epithelium is beginning to grow at the edges and likewise in certain areas over the base of *the ulcer. Important* therapeutic procedures are radical excision, local application of zinc per oxide, and the use of penicillin and other antibiotics.

painful, are tender, and often have a tendency to bleed on the lightest touch. The advancing red or pink edge is sharp and serpiginous and leaves healing granulation in its wake which slowly epithelializes (Fig. 15). Antibiotics *and zinc peroxide should* be tried. *If improve*ment is not marked, excision of the gangrenous area and red border should be carried out because it is so effective. Skin grafting is done at a later date.

Thermal Gangrene. Either excessive heat or freezing will produce gangrene. The destruction of tissue in most burns is confined to the skin and subcutaneous tissue, because of the short exposure. On the contrary, the gangrenous process caused by freezing may include the entire digit or extremity if the member is exposed for hours, as is frequently the case (Fig. 16). See Chapter 15 for detailed discussion.

Miscellaneous Types of Gangrene. A *chemical gangrene* may be produced by spilling corrosive *substances* (e.g., strong *acids* and alkalis) on the skin, or by the intentional application of harmful medicinal agents. The most common example of the latter is the repeated and persistent application of "carbolized petrolatum" (containing varying *amounts of phenol) to lesions on the extremi*ties. Since the phenol acts as a local anesthetic, its "soothing" local effect masks the tissue destruction which is only evident 24 to *48 hours later.* The process of *epithelialization* progresses slowly, following chemical burns. This is decisively illustrated by the slough and sluggish ulcer which develops following the accidental perivascular *injections* of sclerosing solutions (*e.g.*, sodium salicylate) for obliteration of varicose veins, or of calcium salts being injected intravenously. If an acid or strong alkali is spilled on the skin *it would appear* advisable theoretically to treat it with an antidote or antagonistic chemical. Practically, it has been found that the use of large amounts of water is more effective, *because* the application of *an* antagonistic chemical may produce as much damage as the offending chemical, thereby more than offsetting the value of chemical *neutralization.*

Amebic gangrene of the skin is rare, but has been reported in a few instances chiefly as a superficial gangrenous process *complicating abdominal* operations. The lesion is

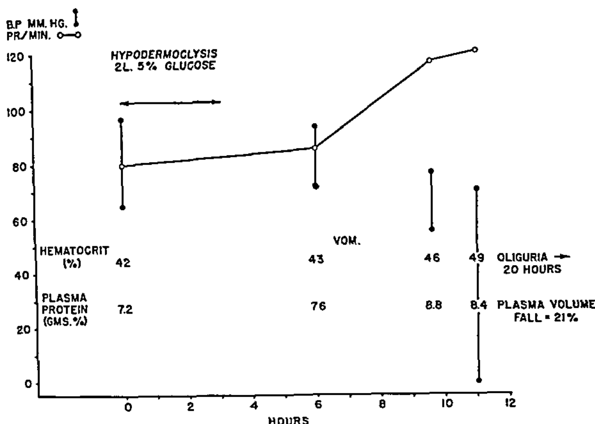

Fig. 1. The hazard of hypodermoclysis with glucose solution. Note the evidence of circulatory impairment and fall of plasma volume following the subcutaneous injection of 2 liters of 5 per cent (isotonic) glucose in a young woman. The changes were due to transfer of water and electrolyte from the blood to the glucose-containing space. Eventually, equilibrium was reached, absorption was completed, and the changes returned to normal. (Courtesy, William E. Abbott.)

sions of the nutritional aspect of surgical therapy may be found in papers or texts by Holden (1), Ravdin (2), Rhoads (3), and Elman (4). Although the problem of therapy is, to a large extent, biochemical, it is readily solved in most cases by relatively simple knowledge of fluid and food requirements in terms of their basic elements. Six primary nutritional substances make up the normal well-balanced diet and, indeed, comprise the essential constituents of body tissue and fluids. They are: 1. water; 2. electrolytes (minerals); 3. carbohydrates; 4. fats; 5. protein; and 6. vitamins. Because fat and carbohydrate can be considered together as supplying calories, five rather than six elements will be discussed below. It may be noted, however, that fat and carbohydrate each serve several extracaloric functions. For example, glucose is important in preventing the acidosis of starvation, especially after operation, but given alone without the required salt can result in actual hypovolemia (Fig. 1).

The basic principle of therapy is the *adequate but not excessive replacement of losses*, both normal and abnormal, by providing an intake of the right kind in adequate amounts, in an appropriate manner, before, during, and after operation or injury. The objective is to restore or maintain normal balance; i.e., to keep the blood and tissues as close as possible to a normal level in as simple a way as possible, and thus to achieve the maximum in rapid and complete convalescence from injury, infection, or operation.

The five nutritional elements or factors enumerated above will be discussed separately, although there is a great dependence of one on the other. For example, water and electrolyte balance may be difficult or impossible to attain unless serious protein deficiencies are also corrected; glucose cannot

Methods of Fluid and Food Administration
Surgical Methods

In his classic observations on physiology, Claude Bernard emphasized the body's need for maintaining a uniform and optimum *milieu interieur,* or body composition, despite external changes imposed upon the body during health but especially in sickness.

Changes in body fluids and tissues can sometimes be detected by chemical examinations of the blood and urine, by measurement of body spaces (compartments) including blood volume, and by tissue analysis. A more direct and bedside approach is knowledge of the intake and output expressed in terms of *balance.* It is a safe assumption in most cases that the composition of the body tissues and fluids is being maintained at a normal level when the intake and output are equal, or, in balance. Deficits follow *negative balance;* that is, when the loss exceeds the intake. On the other hand, to correct a deficit, replacement of the loss means a temporary *positive balance;* that is, retention until the loss is replaced and normal composition is achieved. On the opposite side of this therapeutic coin are the mistakes made by providing too great an intake, more than is needed or can be excreted, thus causing an abnormal retention, or *positive balance.* A common example of the latter is the so-called *salt edema* which follows the excessive infusion of salt solution in patients who, because of renal impairment, cannot promptly excrete the unneeded excess. However, should the edema be successfully reduced through adequate diuresis, a temporary and therapeutic *negative balance* will ensue. Since mistakes in therapy are still common, it will be necessary in this section to describe the nature and therapy of excessive administration of fluids and foods, and discuss deficits from inadequate administration to replace normal or excessive losses.

In mild illness, as in health, intake of the required amounts of fluid and food to maintain normal balance can usually be left to the patient. Because of anorexia, this is not always true in the seriously ill, surgical or medical patient. Indeed, no intake may be possible because of obstruction or vomiting. Added to this decrease in or complete absence of intake, are the abnormal losses seen in surgical patients which increase the degree of negative balance with its ensuing tissue and fluid deficits. To assure a minimum intake of the food and fluid elements necessary to approach or maintain normal balance becomes, therefore, one of the most important responsibilities of the surgeon in the care of his patients. Without such care, operative risks, postoperative complications, and even mortality increase unnecessarily and convalescence is delayed unduly.

The different elements in the body involved in maintaining normal balance or optimum composition of body fluids and tissues are actually the same as the ailments in a normal well-balanced diet. Thus, one is justified in approaching this field of surgical care from the nutritional point of view. Indeed, the American College of Surgeons has recognized its importance by setting up a permanent Committee on Nutrition. Provocative discus-

ELECTROLYTE BALANCE

Electrolytes include many kinds of salts, of which the most important in the extracellular fluid is sodium chloride. Sodium comprises nearly 100 per cent of the cations and chloride 80 per cent of the anions in the extracellular fluid, the rest of the anions being largely bicarbonate.

Sodium Chloride. The minimum intake of *sodium chloride* required for balance, under basic and normal conditions without disease or abnormal losses, is probably less than 1 gm. per day. Ordinarily, however, about 5 to 8 gm. are normally ingested and excreted; the difference is probably largely a matter of taste, the origin of which has had an interesting history (5). Requirements increase tremendously in order 1. to replace losses of electrolyte-containing fluids occurring in excessive sweating, vomiting, fistula, or diarrhea; 2. to replace the extravasation of extracellular fluid into distended loops of bowel or stomach; or 3. to replace fluid loss accompanying large areas of such inflammation as those produced by burns, thrombophlebitis, insect bites, peritonitis, and pleuritis (Fig. 2).

Salt deficiency alone is also called *water intoxication* when it follows the loss of both water and salt, mentioned above, and water alone is ingested or given. First described by Rowntree in 1922, and many times since, it is still encountered all too frequently. An example is the patient with an extensive burn, after severe diarrhea, between bouts of vomiting, or during excessive sweating, who drinks large quantities of water to slake his thirst. Iatrogenic salt deficiency follows the intravenous infusion of glucose solution alone in patients who have vomited considerably or who have drained large amounts of gastric contents through an indwelling catheter. Excessive water intake alone may lead to the same end result inasmuch as the resulting diuresis provokes a normal salt loss in the urine. This was true in one of the first cases of water intoxication reported (6), in 1938, of a woman who, after hysterectomy, was allowed to absorb huge amounts of tap water per rectum through a continuous proctoclysis. Her life was saved by prompt administration of sodium chloride. Plasma sodium in these cases is unusually low. In water intoxication, mental symptoms dominate and may be associated with convulsions. A mistaken clinical diagnosis of cerebral vascular accident is thus often made, especially in older patients.

Sodium chloride deficiency, when allowed to develop to a serious degree because of excess unappreciated losses, results in mental confusion and finally *shock* with absent radial pulse. It responds miraculously to sodium chloride therapy.

Combined water and electrolyte deficiencies are perhaps the most common and follow unreplaced losses as mentioned above. Clinical manifestations are usually called *dehydration* or *anhydremia,* although strictly speaking these terms should be reserved for water deficiency alone. The signs and symptoms vary considerably, depending upon the severity and duration of the loss, and upon the rapidity with which it has occurred. A deficit of water and salt should always be suspected in any patient in whom there has been a history of water deprivation and low urinary output for several days; particularly when abnormal losses have been inadequately replaced. The dehydrated patient exhibits a general dryness of the body tissues, especially of the tongue and mucous membranes. The eyes and cheeks are often sunken in severe cases, a phenomenon which has been described as "Hippocratic facies." Mental apathy may even lead to coma. Subjectively, the patient first complains of weakness and anorexia and, when water loss is predominant, of extreme thirst. Vomiting itself is not uncommon, even without the ingestion of fluid. When there is a rapid loss of fluid, shock may occur, especially when plasma is also lost as in peritonitis, acute intestinal obstruction, hot water burns, and, occasionally, in extensive cellulitis or inflammatory edema of an entire extremity in thrombophlebitis. The most dramatic picture, after severe persistent losses through vomiting and constant purging, used to be seen in cholera victims, many of whom became comatose, wasted, shriveled, and actually went into shock within a matter of hours or days.

Water and electrolyte excess results from mistakes in therapy during which more sodium chloride solution is injected than is needed or can be excreted by the kidneys. This is commonly true after operation, or

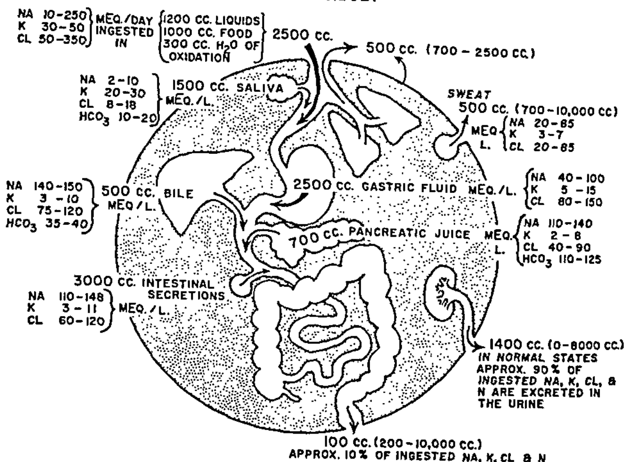

Fig. 2. Normal water and electrolyte exchange. The diagram summarizes the various kinds of fluid exchanges, then amounts and approximate composition under normal conditions. On the right, the arrows indicate the water and electrolyte output due to (*a*) insensible loss through lungs, skin, and as sweat; (*b*) urine; and (*c*) feces. Under normal conditions, balance is achieved because these losses add up to the oral intake. The losses under abnormal conditions are shown in parentheses. (Courtesy, William E. Abbott.)

be metabolized normally without adequate supplies of thiamin; protein utilization is greatly affected by the intake of carbohydrates.

FLUID BALANCE

Water, though the simplest, is also the most essential food element, since without any water intake, even though other elements are supplied, life is impossible for longer than a week or ten days in man. Water comprises 70 per cent of the total weight of a lean, almost fat-free adult. In a 70-kg. man this comes to 50 liters, of which 14 liters represent extracellular fluid (3 liters as plasma, the rest as interstitial fluid). The largest part, or 36 liters, comprises intracellular water. In a normal adult, balance is achieved with an intake of about 2 liters of water per day or 30 ml. per kg.; in the newborn, it approaches 100 ml. per kg. This intake permits the normal kidney to excrete all waste products and to replace the insensible losses without leading to water deficiency (Fig. 2).

Water deficiency alone follows complete deprivation of water since insensible water loss is obligatory and cumulative; added to this is a continued though diminished urinary output. A more severe and rapid water deficiency follows increases in insensible water loss, in fever or high environmental temperature with low humidity, unless, of course, the loss is replaced. The clinical picture, often called dehydration, is that of extreme dryness of the tissues, profound thirst, and mental apathy. Water deficiency in disease is actually more commonly associated with a deficiency of electrolytes and is, therefore, discussed in the next section.

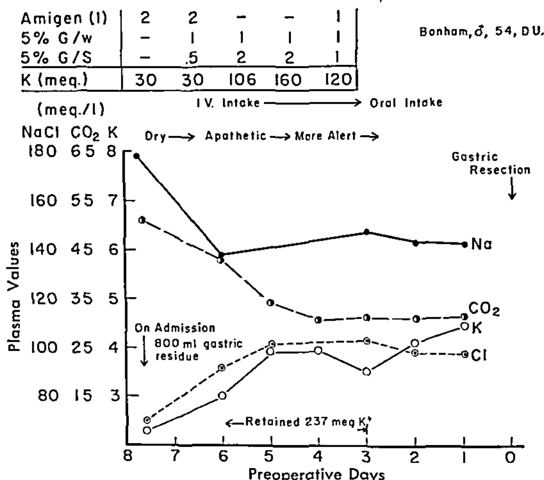

Fig. 3. Potassium deficiency in a patient with pyloric obstruction. The patient was a 54-year-old mechanic with a long history of duodenal ulcer, including periodic pyloric obstruction and loss of weight. After eight days of preparation, adequate gastric resection was carried out, followed by a gastroduodenal anastomosis. Normal oral intake was reached by the sixth and the patient was discharged on the eighth postoperative day. Since then he has remained free of symptoms and has gained 30 pounds in weight.

Note especially in the data above the high plasma sodium and low potassium levels on admission, indicating unreplaced water and potassium loss, and the low chloride and high CO_2 levels (hypochloremic alkalosis), characteristic of loss of acid gastric contents and of potassium deficiency. These biochemical findings could have been predicted since only isotonic sodium chloride had been previously given without water (as glucose and amino acid solution) or potassium. The failure of previous saline therapy alone to correct the potassium and insensible water loss emphasizes the need for attention to all elements in replacement therapy.

The relief of pyloric obstruction before operation indicated that spasm, edema, and gastric atony were largely responsible. Gastric atony can be produced by intracellular potassium deficiency, which, in this case, was corrected by a total intake of 28 grams (440 mEq.) of potassium chloride. Note that only 18 grams (237 mEq.) thereof were retained because of the inability of the kidney to completely conserve K^+ even during a deficiency. Note also that a maximum of 4 grams (53 mEq.) of KCl were added to each liter; higher concentrations may lead to pain and phlebitis.

Preoperative preparation, as illustrated in this case: (*a*) reduces the technical difficulties at operation by reducing edema of the stomach wall and in the pylorus; (*b*) lowers operative mortality by correcting serious biochemical deficiencies, which always increase risk; and (*c*) shortens the period of convalescence by promptly restoring normal gastrointestinal function.

when more simple means prove ineffective, and when there is a fair chance that renal function is not irrevocably lost.

The role of magnesium in electrolyte deficiencies is difficult to evaluate particularly since accurate measurement is difficult. The

when the patient suffers protein deficiency. The usual outcome is edema, often called "salt edema," leading to wound disruption, leakage or obstruction at gastrointestinal anastamoses, and pulmonary edema. Retention of fluid in this way is to be suspected when the urinary output is unusually small following the administration of large amounts of salt solution. Once edema develops, it is difficult to relieve. Prevention is thus far better than cure.

Potassium. Knowledge of the clinical importance of potassium has greatly increased within the past decade, thanks to the development and wide use of modern flame photometry (7), with which the plasma and urinary potassium can be accurately and rapidly measured in any good clinical laboratory. *Since the whole body potassium is almost entirely intracellular, the plasma level is quite low, i.e., only 4 to 5 mEq. per liter, in contrast to a value of 140 mEq. for sodium.* Nevertheless, low levels, down to about 1 mEq. per liter, have been found in potassium deficiencies, and high values, above 7 mEq. per liter, in certain cases of renal insufficiency. Plasma levels, it should be emphasized, do not necessarily reflect intracellular levels which often are of much greater importance (see below).

Perhaps the most common condition leading to *potassium deficiency* is that which follows correction of water and salt deficits with *saline solution alone, when electrolytes are being lost by gastric decompression* (Fig. 3) *or some similar mechanism.* What happens is that, with the restoration of the urinary output, large amounts of potassium are lost in the urine due to the relative inability of the kidneys to conserve potassium. Another type is the hypokalemia (hypopotassemia) associated with persistent postoperative hypochloremic alkalosis uninfluenced by an increased salt intake (8). The mechanism is not entirely clear, but the blood chemical changes and clinical manifestations can be corrected readily by the administration of potassium. Recognition of potassium disturbances is often hampered by the need for distinguishing between intracellular and extracellular deficits. The latter can be detected by finding a low plasma level. The former can be determined only by measuring intake and output of fluid, and finding that potassium administration leads to a positive balance, thus indicating the therapeutic retention of this salt (9). *Another disturbance which requires further study is the loss of intracellular potassium, with its replacement by sodium, owing to altered cellular permeability or actual cell damage, often associated with the effect of adrenocortical steroids.*

Potassium deficiency produces a variety of clinical manifestations depending upon the severity and rapidity of the loss. Mental apathy, even disorientation, is frequently seen. There is muscular weakness and gastrointestinal paralysis often simulating intestinal obstruction or paralytic ileus. Potassium deficiency can often be prevented by including a small amount of potassium in the intravenous fluids. Correction of potassium deficiency is often difficult, particularly when the parenteral route alone must be used, *because potassium chloride is irritating to the vein in concentrations above 4 gm. per liter.* Since total deficits up to 75 gm. or more of KCl may occur, and since but half the infused salt may be retained, a week or more is often required to correct a severe deficiency. Concentrated solutions of KCl, made to supplement other solutions, must never be injected, as such, into a vein because of the danger of cardiac arrest.

Increased potassium levels are associated with renal insufficiency, and may be *high enough to produce signs of potassium intoxication* which are similar to those of uremia. The electrocardiogram is much more valuable in the diagnosis of high potassium plasma levels than it is for low potassium plasma levels. Therapy is that for renal insufficiency. Also of value is the slow infusion of 25 per cent glucose (with increase of glycogenesis) and of sodium bicarbonate (alkalosis increases and acidosis decreases the *movement of potassium from the plasma to the cell).* *Administration of cation exchange resins* when properly given, even per rectum, has proved a simple and often an effective way of reducing a high potassium plasma level. The artificial kidney has been widely used and will undoubtedly and effectively lower the high plasma level of potassium and urea with obvious clinical benefit. *Its practical application is not easy and should, therefore, be used only*

CALORIC NEEDS

Calories are next in importance to water. In the normal diet, calories are provided by the intake of carbohydrate and fat, whereas during caloric deprivation the energy needs are supplied by the breakdown of fat and muscle tissue, because there is no significant storage of carbohydrate in the body. The depletion of adipose tissue is, of course, physiologic, particularly when fat is present in large amounts. On the contrary, the loss of protein tissue is undesirable (see below).

For a normal adult at rest in bed, caloric balance with no loss of body tissue can be met with a basal intake of 1,500 to 2,000 calories, or, about 25 calories per kilogram of body weight. In infancy, the comparable figure is 60 calories per kilogram of body weight. These needs are increased in fever. In most surgical patients immediately after operation, it is difficult or impossible to maintain such a high intake, particularly when only the parenteral route is available. Some limitation in the total intake is, therefore, temporarily necessary in most cases. Since 80 to 90 per cent of the bulk of the normal diet consists of carbohydrate and fat, one is justified in temporarily reducing the total intake thereof rather than that of protein, which indeed occupies but a small portion of the bulk of the normal diet. The reasons for this are many; the main one is that the inclusion of protein even in the subcaloric intake reduces the degree of tissue protein depletion as compared with a protein-free intake. When full caloric intake cannot be achieved it is far better to ensure an intake of about 1,000 calories and to include an adequate amount of protein rather than to leave the intake to chance or limit it entirely to carbohydrates. In the case of patients able to drink but not chew, a liquid intake can readily be provided. The same principles apply when the parenteral channel is indicated. About 800 calories are the maximum that can be given in 2 liters of 10 per cent intravenous glucose. Ethyl alcohol may be added as a source of more calories (16), but the side effects seem to preclude its use as routine. Emulsified fat is utilized when given intravenously and will aid in solving the problem of adequate parenteral caloric needs. A new product which is comparatively free from reactions (17) may meet this urgent need. Fructose rather than glucose has certain advantages, especially in reducing the loss of sugar in the urine and in avoiding postinfusion hypoglycemia (18, 19). In severe malnutrition it will be necessary to increase the caloric intake to several thousand per day to achieve satisfactory nutritional rehabilitation.

PROTEIN NEEDS

Protein needs are so much more important to the surgical patient than carbohydrate and fat as described briefly above, that protein metabolism will be discussed in detail under a separate heading. Acute protein losses, such as sustained in hemorrhage and acute inflammation (e.g., burns, peritonitis), can usually be met by transfusion of blood or plasma as discussed later. More chronic protein deficiencies are due to persistent negative protein (often called nitrogen) balance and are frequent especially in surgical patients. Under normal conditions, protein balance can be achieved with an intake of about 1 gm. per kilogram or about 70 gm. per day. However, an increased tissue protein breakdown known as the "catabolic phase of injury," may lead to the wastage of as much as 250 gm. of tissue protein a day, or three times the normal intake. It is obvious that increasing protein deficits will follow such large losses unless they are adequately replaced. Nevertheless, because surgical patients immediately after operation usualy have severe anorexia, protein intake falls to zero so that protein deprivation is added as another factor leading to an increasing degree of negative balance.

Protein deficiency should always be suspected in any patient with inadequate intake, particularly in the presence of excessive protein losses. Blood chemical measurements may reveal such a deficit in the form of a low plasma protein concentration, called hypoproteinemia. The most important plasma protein fraction in such cases is albumin, which can also be readily measured. Hypoalbuminemia may also be due to actual loss, as in hemorrhage, burns, or extravasation of various kinds; also, to deficient formation of pro-

blood level is too low for the application of flame photometry. A recent study of deficits in man has been reported by Fink (11).

THERAPY OF WATER AND ELECTROLYTE IMBALANCES

In order to prevent deficiencies and to avoid excessive intake, one may start with the routine needs for water and electrolytes in a normal adult maintained on parenteral fluids after operation. In such a case, about 2 liters of water per day are probably sufficient. Of this, 1 liter will be needed for urinary excretion and 1 liter for insensible losses and any small amount of abnormal loss. The electrolyte intake should include sodium, potassium, chloride, and phosphate. Such a mixture was used in a series of cases (12) and shown to meet the daily maintenance needs of the average postoperative patient without leading to excessive retention. As mentioned later, the intake should also include carbohydrate and, preferably, amino acid mixtures.

The therapy of existing deficiencies depends primarily upon the history and clinical manifestations. Measurements of the serum sodium, chloride, and bicarbonate levels and of urinary chlorides are also helpful as a guide to therapy, but are not absolutely essential and may be misleading. In pure water deficiency, several liters of water plus a few grams of sodium chloride are all that are required. Parenteral infusion, when indicated, should contain largely glucose and amino acids and should be continued until diuresis is established. Many such solutions are available containing necessary but minimum amounts of the electrolytes mentioned above. In combined water and salt deficiency, isotonic saline or, preferably, physiologic saline is indicated. Some colloid, either blood, plasma, or a substitute, should be added whenever the loss occurs into the tissues, as in inflammatory edema, and particularly when shock is present. When the loss occurs into the tissues, control of shock is the primary indication for therapy. Reabsorption and excretion of the fluid by the kidney will occur sooner or later. Not only must excessive infusion be meticulously avoided but the amount and rate of infusion should be reduced to the minimum needed to maintain the circulation. In salt deficiency (water intoxication), isotonic saline may be effective, but hypertonic salt, up to 5 per cent in doses of 200 ml. for an adult, is preferable, especially when edema is present. In "salt edema" a pure water intake aided, perhaps, by a mercurial diuretic may be effective. Hypoalbuminemia or anemia should also be corrected simultaneously.

The reader is referred to a number of excellent texts in which the various types of water and electrolyte deficiencies are discussed in great detail (13, 14, 15). For purposes of simplification, three of the more common types of water and electrolyte deficiencies are briefly described in Table 1.

TABLE 1. Commoner Types of Water and Electrolyte Disturbances

NAME	PATHOGENESIS	MECHANISM	EXAMPLES	THERAPY
1. Water deficiency (dehydration)	No replacement of normal (or excessive) cumulative insensible water loss	Thirsting, hot, dry environment, fever	Esophageal or pharyngeal obstruction, "life-raft victims"	Large water, little salt* intake
2. Water and salt deficiency (dehydration)	No replacement of abnormal losses of fluid containing electrolyte	Vomiting, diarrhea, excessive sweating from fever, or hot, humid environment, inflammitory extravasation	Pyloric obstruction, intestinal obstruction or fistula, ulcerative colitis, hot-water burns	Large water and salt* intake
3. Salt deficiency (water intoxication)	Excessive water intake with normal or excessive salt loss	Same as above, plus pure water replacement	Infusion of glucose solution, or drinking pure water after water and salt losses	Large salt* and little water intake

* Salt refers to sodium chloride preferably with added bicarbonate or lactate.

sues. This process, however, is inefficient, expensive, and slow.

Protein intake is probably undesirable during the acute phase of renal impairment because it increases the degree of nitrogen retention in the blood and tissues. A protein-free (and limited water) intake is therefore indicated. In severe hepatic insufficiency, the oral protein intake should be kept at a moderate level because the digestion and absorption of large amounts of protein (which occurs inadvertently in severe intraintestinal hemorrhage) may be harmful by increasing the blood ammonia level, which seems in some cases to induce or aggravate existing hepatic disease, even to the point of coma.

VITAMINS

Vitamins are, of course, an essential part of the dietary intake and are indicated in all surgical as well as other patients. It is difficult or impossible to measure vitamin balance. Moreover, vitamin deficiencies are seldom seen clinically even in the malnourished patient. The need for many vitamins (25), however, especially vitamin C, is apparently greatly increased after injury. Since excessive intake of most vitamins is apparently harmless, there is usually no particular problem in providing a large and adequate vitamin intake. A small pill by mouth or a small ampule by injection supplies the daily requirements. Pure mixtures of the most important vitamins are now available and, actually, are seldom missing from the intake of all patients, whether their food is taken by mouth or by infusion.

METHODS OF FLUID AND FOOD ADMINISTRATION

Although it is possible in most cases to provide an adequate intake by the oral route, the parenteral channel is sometimes indicated. Each will be discussed separately. Transfusion may be needed in either case.

Oral Administration. The oral route should be used whenever possible. In the face of severe anorexia, however, special attention on the part of the surgeon, and sometimes individualized nursing care, may solve the problem of assuring an adequate intake. Occasionally persuasion is effective. Hypnosis has even been used with apparent success (26). If the patient will take liquids but refuses to chew solid foods, a palatable drink can readily be provided which contains each of the essential nutritional elements, as already discussed above. The help of a good dietitian is often invaluable. In order to restore the severely malnourished as well as to provide a minimum intake for the acutely ill, the initial caloric intake should be low to avoid vomiting, distension, and diarrhea, but should be increased as rapidly as possible. In many cases a high fat intake, in spite of its caloric superiority, is not recommended because it slows the emptying of the stomach and tends to decrease appetite.

Tube feeding may be necessary to assure an adequate intake if the patient is unconscious or is unable or unwilling to swallow a full liquid diet. Many former difficulties with tube feeding have been solved so that this method is now simple and safe, thanks to the use of a small-gauge plastic tubing which is nonirritating and scarcely noticed by the patient. However, it requires a feeding formula which does not block the narrow lumen of the tube. A widely used, finely divided powder suspended in water has proved quite satisfactory (27). A gastrostomy similarly permits fluid and food intakes in patients with esophageal obstruction. A jejunostomy, when the obstruction is beyond the stomach, does the same.

Only simple fluids such as water and saline solution can be given effectively by rectum (proctoclysis). Popular decades ago, proctoclysis is seldom used at present. One difficulty is rectal irritation, which soon leads to expulsion of the solution. The rectal route is often utilized in patients who cannot take anything by mouth for the administration of such drugs as paraldehyde, chloral hydrate, dilaudid suppositories, and many others.

Parenteral Administration. This method for the provision of fluid and food intake ranks with other great advances in surgery in that it has extended the frontiers of disease now amenable to operation. By aiding in preoperative preparation, it has gradually reduced risk; by preventing or correcting acute deficits during and after operation, it has minimized complications, lowered mortality, and shortened convalescence.

tein, as in liver disease, as well as to protein starvation itself. Hypoalbuminemia, when severe, will lead to nutritional edema; i.e., edema which is not cardiac or nephritic, but which follows the lowered colloidal osmotic pressure of the plasma resulting from fall in the level of plasma albumin. Other such factors as gravity, venous pressure, exercise, tissue tension, or the intake of unneeded salt, are also important in precipitating nutritional edema. Nutritional edema is of great importance in the surgical patient for many reasons, not only because it may be associated with pulmonary edema and because it delays healing (20), but also because it may be present in the mucosa of the intestinal tract, which interferes with normal gastrointestinal function and often produces obstruction at a gastrointestinal anastomosis (21). This was first observed by Jones and Eaton (22) in 1933. Other clinical manifestations of protein deficiency are asthenia, anorexia, hepatic impairment, defective wound healing, and increased susceptibility to shock and certain infections, notably tuberculosis.

Therapy of Protein Deficiency. Nowhere is it more true than in protein nutrition, that an ounce of prevention is worth a pound of cure. Protein deficiencies may be prevented, first of all, by avoiding protein starvation and, secondly, by replacing abnormal losses in the blood soon after they occur. Protein starvation can be avoided by ensuring an adequate nutritional intake from the very beginning of disease, using protein-containing liquid drinks, when necessary, or a parenteral intake containing amino acids (hydrolyzed protein), if indicated. Deficiency due to abnormal blood losses can, of course, be prevented by adequate and prompt transfusions.

To correct existing tissue protein deficiencies, amino acids are required either from digested protein taken by mouth or given as such intravenously. Existing blood protein deficiencies, however, are much more readily and rapidly (even though temporarily) corrected by transfusion, particularly in preparation for operation. Significant tissue protein deficiencies require large amounts of protein, often up to 1,000 gms. or more, amounts which call for "hyperalimentation," often by tube feeding. This is usually impossible before most abdominal operations and must await the removal of the gastrointestinal lesion before full restoration is possible. In such a case the oral route can then be used. The parenteral channel is indicated whenever the gastrointestinal tract cannot or should not be used. For the correction of large tissue protein deficits, parenteral protein feeding is somewhat limited in scope, although the equivalent of 75 gm. per day can be given without too much trouble. While it is possible to prevent further tissue protein depletion in this manner one can, at most, expect only moderate correction of existing deficiencies. Moreover, it is a good policy to avoid complete protein starvation by adding a protein hydrolysate to the usual intake of water, glucose, and vitamins. This is especially true of the depleted patient being prepared for operation and even for the well-nourished patient requiring parenteral alimentation for more than a day or two after operation. Protein feeding with the intravenous infusion of amino acid mixtures is just as physiologic as the infusion of glucose; both are temporarily indicated whenever the gastrointestinal tract cannot or should not be used.

Completing the intravenous diet by the addition of protein food in this way was introduced (23) nearly 20 years ago. It has already been used extensively and may now be considered as a routine method of therapy for those unable to take any food by mouth. The principles involved are the same as those in the patient with severe anorexia, yet able to take a liquid diet by mouth. Protein starvation, regardless of its cause, promotes anorexia (24) and thus prolongs healing as well as convalescence. Extensive clinical experience has shown the importance of maintaining an adequate protein intake from the beginning of disease, an objective which is now a relatively simple matter whether or not the patient can take enough protein by mouth.

Plasma or blood transfusions also provide protein through the intravenous channel largely as a means of correcting chronic hypoproteinemia and anemia. Blood and plasma can also correct tissue protein deficits by a roundabout metabolic pathway, aided by tissue proteases which break down the plasma proteins or hemoglobin molecules, after they leave the blood stream, into their constituent amino acids which are then used by the tis-

sary, for the effective treatment of the patient whether operation is performed or not.

While the operation in most cases demands first consideration, many of the nonoperative procedures are sometimes *of equal importance* in securing a successful end-result. Most of these procedures, including the administration of drugs, should be used with the realization that their effects are not always predictable. For this reason, much commonly used therapy should be regarded as experimental. If this is done, it will soon be apparent that there are great *individual variations* in the response of patients, even of the same sex, age, and size—variations which are due *to many factors, some unknown. By combining* careful observations with the experience of others, one can establish the value or lack of value of each type of therapy. Although principles are really more important than details and must never be forgotten, it is really a combination of attention to scientific knowledge and the findings based on clinical experience that will permit each physician to reach the highest level of therapeutic efficiency. This approach will be used in the following discussions.

Rest: General and Local. Rest is probably one of the oldest single agents used in the treatment of surgical disease. Although its useful application is often taken for granted, there are many disadvantages which must be recognized. Thus, rest should not be employed when not indicated, nor for too prolonged a period. Both the advantages and disadvantages of general and local rest will be emphasized in the following discussion. In many instances rest may be modified or combined with limited motion, thus utilizing the benefits of each.

General rest means complete confinement to bed. In most cases movement in bed is permitted and, in fact, encouraged.

General rest implies not only physical rest of the body as a whole, but mental rest as well. The latter is often overlooked or its significance minimized. Surgeons are apt to forget the influence of mind over matter. Yet there is ample evidence that the patient whose fears have been allayed, whose muscles are relaxed, who sleeps well, has no pain, and has implicit faith in his doctor, will combat the effects of infection and injury much better than one who is apprehensive, tired, and worried. Ignorance itself is an important element in fear. All of these factors must be considered by the surgeon in planning his *general therapeutic program. The many im*plications of psychogenic factors in surgical diseases have been discussed by one of the authors in a text on surgical care (28).

Although general rest implies complete bed rest, it may be modified by permitting bathroom privileges, or the use of a commode in order to avoid a bed-pan and urinal, which may be annoying, particularly to male patients. Most surgical patients, though at rest in bed, should be encouraged and even or*dered to move their extremities and to do* deep respiratory exercises. The former will combat the tendency to deep plantar vein thrombosis (which often sets the stage for fatal pulmonary embolism) probably as effectively as early ambulation. Moreover, muscular movements minimize atrophy of disuse, anorexia, certain cardiovascular changes, and invalidism. Deep respiratory movements increase pulmonary ventilation and thus combat the tendency toward passive hyperemia of the lungs and postoperative atelectasis.

Local rest means rest of an individual part or system and may be used either alone or in conjunction with general bed rest. Narcotics add much to comfort of patients but they depress respiration and the cough reflex. A tight chest binder reduces pain by limiting respiratory movement in fractured ribs, yet in doing so actually permits full aeration of the lungs. The gastrointestinal tract is put at rest by ordering "nothing by mouth" in order to limit the degree of intestinal movement. In the case of the stomach, however, the situation may be different, at least in the presence of an active peptic ulcer. In this case, gastric peristalsis is generally increased when the organ is empty, which may be harmful by increasing pain and bleeding. For this reason the ingestion of food, particularly food containing fat, decreases gastric peristalsis and tends to minimize pain and further bleeding. At the other end of the gastrointestinal tract, defecation can be prevented by the use of constipating drugs while rectal wounds are healing.

Local rest of a part is used chiefly in cases of infection of, and injuries, fractures, and

Two general channels are commonly used for parenteral injection or infusions: one is subcutaneous (hypodermoclysis) and the other intravenous. Since each requires the use of the hollow needle, the details are discussed under that heading.

The *various fluids* which are commonly used, singly or in combination, for parenteral injections are: 1. whole blood; 2. plasma; 3. pure human serum albumin solution; 4. packed red cells; and 5. aqueous solutions containing (*a*) sodium chloride, bicarbonate (or lactate), and phosphate, (*b*) potassium chloride, (*c*) calcium gluconate, (*d*) glucose, fructose, or invert sugar, (*e*) amino acids (hydrolyzed protein), (*f*) fat emulsions, (*g*) ethyl alcohol, and (*h*) vitamins. Many of the electrolyte and carbohydrate solutions are used in various concentrations to meet different conditions. With such a wide variety, it is not surprising that many physicians find the field of parenteral alimentation complex and sometimes baffling. As already discussed, the problem is most readily solved by attention to the patient's history, to a knowledge of the principles of prevention, and to accurate replacement of specific deficits. Plasma and whole blood are often used to correct hypoproteinemia. When the erythrocyte count approaches normal, blood can no longer be used. As much as 500 ml. of plasma can be given per day, but if more than this is given in a 24-hour period, it will be utilized very inefficiently.

At times, it is essential to make up deficits rapidly. The best example of this is the use of plasma and blood transfusions following hemorrhage or traumatic shock due to loss of blood and plasma, where a delay of an hour or two may be responsible for irreversible circulatory failure and death. A second example would be severe dehydration in which water and salt may have to be injected rapidly when the patient is in a critical condition. However, in such cases the need for speed may be less important than the fact that the gastrointestinal tract is obstructed and cannot be used. When *acidosis or alkalosis* is present, rapid administration of parenteral fluids may be indicated. Ordinarily as dehydration is corrected, resumption of renal activity soon rids the body of excessive acid or base, as the case may be. Occasionally, however, the action of the kidneys is too slow or is handicapped by impaired renal function, and special solutions must be used. This is particularly true of metabolic acidosis, which is relatively easy to combat by the intravenous infusion of sodium bicarbonate or sodium lactate. Acidosis may be detected and measured readily by the degree of fall in the carbon dioxide component of the blood (*normal—50 to 60 volumes per cent or about* 25 mEq. per liter). It is more frequently recommended that sodium bicarbonate or sodium lactate be added to all saline solutions in the proportion normally present (1:3) in the extracellular fluid. Such a solution represents a true physiologic saline solution. Alkalosis seldom requires intravenous acidic (e.g., ammonium chloride) solutions because ordinary therapy usually suffices. Moreover, alkalosis is seldom associated with acute circulatory impairment, metabolic disturbances, or renal dysfunction. As already mentioned alkalosis associated with hypochloremia and hypokalemia responds to potassium therapy.

Often indeed, the parenteral administration of fluids is *the only or the most effective method* of therapy. The best example of indication for the parenteral route is the need for maintaining nutritional intake immediately after operation when oral intake is impossible or is interrupted lest it induce vomiting and distension. Parenteral feeding is also similarly indicated in preparing the depleted patient for operation even though only partial or temporary correction may be possible unless a moderate amount, at least, can be taken by mouth. A third example concerns any patient, medical or surgical, in whom oral ingestion of fluid provokes vomiting, distension, or severe diarrhea, or is injurious because of the need for temporary gastrointestinal rest. Parenteral alimentation may also be necessary in a few cases where there is faulty assimilation of food taken by mouth.

With the availability of amino acids and pure vitamins, an almost complete parenteral diet can now be given. This advance permits the patient to clear temporary nutritional hurdles without starvation.

SURGICAL METHODS

Besides operative therapy, numerous *surgical methods* are available, and in fact neces-

applied when swelling is already pronounced may lead to inadequate immobilization when the swelling subsides. Both can be avoided by frequent observation and adjustment. The Thomas splint is especially useful for immobilizing the upper and lower extremities and will be described later under fractures.

4. *Plaster casts* are commonly used for immobilization in fractures not only of the extremities but also of the pelvis, spine, and neck. The term *hip spica* is used when the lower torso and leg are encased, thus immobilizing the hip. A *shoulder spica* is a similar arrangement about the upper arm and chest. A plaster cuirass is a body and neck cast used to immobilize the cervical spine, because it looks so much like the metal breastplates worn by the ancient knights. Plaster casts may soften from use or by soiling and may have to be replaced.

Plaster casts, perhaps because of the high degree of immobility produced, are much more likely to promote atrophy of disuse. This may be minimized by splitting the cast in half (bivalving), thereby allowing motion under control for short periods between which immobilization continues. Splitting of the cast may be necessary for dressing wounds and occasionally because of circulatory impairment, which should be expected whenever swelling occurs after the cast is applied. The toes or fingers distal to the cast must be observed for 24 hours. Coldness, tingling, numbness, blanching, and cyanosis are manifestations of circulatory impairment. On the other hand, plaster applied when swelling is maximal may become too loose to immobilize the part when the swelling subsides.

Bandaging. Bandaging, once a sort of minor art in surgery, now deserves no such designation. The technic of bandaging with the older roller gauze made of thick muslin required special training, and courses in bandaging were given in most medical schools. With the advent of the thinner gauze bandage the situation changed. Bandages used at present are applied with much greater ease and really require no special technic. A bandage serves the purpose not only of rest and immobilization, but also of holding dressings in place and of protecting wounds against contamination. Bandages over exposed parts of the body also minimize heat radiation, thus inducing a higher local temperature which aids repair by increasing local blood flow. Bandages may be made of rolls of gauze, muslin, linen, or synthetic materials. Wide strips (binders) are used around the chest and abdomen. A popular form of binder is the many-tailed or scultetus binder. The sling has already been described.

There are many types of bandages which can be applied with a roll of gauze (Figs. 6, 7, 8). The *circular* or *spiral bandage,* as its name implies, is used to cover the sides of an extremity or finger. If the tip of the finger is to be covered or an amputation stump dressed, recurrent layers are first placed over the end and the dressing called a *recurrent bandage*. The *figure-of-eight* is a widely used type which consists of two crossed loops of gauze. When used to immobilize a joint—as the knee, elbow, or ankle—the loops are placed on either side of the joint. When the loops are passed around each shoulder, crossing between the scapulas, traction can be applied to the clavicles. This is a useful bandage for fractures of the clavicle. A *gauntlet bandage* is really a figure-of-eight in which one or more fingers are embraced in one loop and the wrist by the other, the bandage crossing over the dorsum of the hand. A *spica bandage* is applied in a manner similar to a plaster spica, as already described, but gauze alone is used.

Special bandages go by the names of their inventors. Thus *Barton* described a head bandage in which the roll of gauze is made to form three loops, one encircling the head longitudinally in front of the ears, the second horizontally just below the lip, including the chin and passing below the ear, and the third obliquely joining the first two and passing from the top of the head around the occiput. It is used in various head injuries. A *Velpeau bandage* serves to bind the arm to the chest and to elevate the arm. The hand is first placed on the opposite shoulder, the elbow resting against the chest wall. One turn of gauze passes around the shoulder and the flexed elbow, the other encircles the arm and chest. However, this dressing or bandage is so uncomfortable that it is now used only occasionally.

Heat and Cold. One must distinguish between the effects of heat and cold. The latter

sprains to an extremity. Complete immobilization may be indicated, although lesser degrees of immobility are often sufficient. Historically, lively controversies were frequent and perhaps still occur between the advocates of rest and movement. The topic is entertainingly discussed by Keith (29). Limitation of motion often controls pain immediately, relieves apprehension, reduces reflex vasospasm, and thus promotes blood flow. Moreover, in infection, mechanical spread of bacteria into adjacent tissues is minimized by immobility. On the other hand, local rest, if prolonged, leads to reduced blood flow, decalcification of bone, atrophy of muscles, and limitation of movements of joints and tendons which, in older individuals especially, may even be followed by complete and permanent disability of the part. This is called *atrophy of disuse*.

METHODS OF IMMOBILIZATION. The various methods used to achieve immobilization in order of the degree of their completeness are: 1. slings and other bandages; 2. adhesive strips; 3. splints, and 4. plaster casts. Bandaging in general will be discussed separately.

1. A *sling*, usually made of muslin, is the simplest way to rest the upper extremity (Fig. 4); it may be made to include the hand. With the corners of the sling tied tightly behind the neck, the hand and forearm may be brought high up on the chest, increasing the degree of immobilization and also producing elevation of the forearm. A useful modification of the sling is the so-called *collar-and-cuff* (Jones) *sling*, which can easily be adjusted to any length allowing any degree of flexion of the elbow.

2. *Adhesive strips* are used to immobilize the elbow in flexion, the ankle in either eversion or inversion, the patella (to a slight extent), the ribs, the pelvis, and sacroiliac joints. Adhesive is also used to hold dressings in place. Adhesive may produce dermatitis which can sometimes be avoided by using Scotch tape instead.

3. *Splints* are made of wood, metal, or plaster. The wooden boards are thin and cut to proper size and shape (Fig. 5). Padding is added to the side next to the skin. Such rigid support prevents motion and is especially necessary in bone and joint injuries. The danger of excessive pressure under splints is greatest when the part is immobilized before swelling occurs. On the other hand, splints

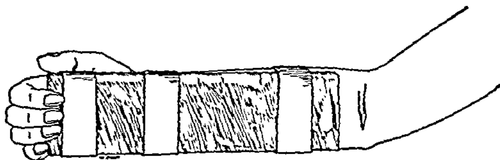

Fig. 5. Immobilization of the wrist and forearm by means of a thin board splint held in place by strips of adhesive.

applied when swelling is already pronounced may lead to inadequate immobilization when the swelling subsides. Both can be avoided by frequent observation and adjustment. The Thomas splint is especially useful for immobilizing the upper and lower extremities and will be described later under fractures.

4. *Plaster casts* are commonly used for immobilization in fractures not only of the extremities but also of the pelvis, spine, and neck. The term *hip spica* is used when the lower torso and leg are encased, thus immobilizing the hip. A *shoulder spica* is a similar arrangement about the upper arm and chest. A plaster cuirass is a body and neck cast used to immobilize the cervical spine, because it looks so much like the metal breastplates worn by the ancient knights. Plaster casts may soften from use or by soiling and may have to be replaced.

Plaster casts, perhaps because of the high degree of immobility produced, are much more likely to promote atrophy of disuse. This may be minimized by splitting the cast in half (bivalving), thereby allowing motion under control for short periods between which immobilization continues. Splitting of the cast may be necessary for dressing wounds and occasionally because of circulatory impairment, which should be expected whenever swelling occurs after the cast is applied. The toes or fingers distal to the cast must be observed for 24 hours. Coldness, tingling, numbness, blanching, and cyanosis are manifestations of circulatory impairment. On the other hand, plaster applied when swelling is maximal may become too loose to immobilize the part when the swelling subsides.

Bandaging. Bandaging, once a sort of minor art in surgery, now deserves no such designation. The technic of bandaging with the older roller gauze made of thick muslin required special training, and courses in bandaging were given in most medical schools. With the advent of the thinner gauze bandage the situation changed. Bandages used at present are applied with much greater ease and really require no special technic. A bandage serves the purpose not only of rest and immobilization, but also of holding dressings in place and of protecting wounds against contamination. Bandages over exposed parts of the body also minimize heat radiation, thus inducing a higher local temperature which aids repair by increasing local blood flow. Bandages may be made of rolls of gauze, muslin, linen, or synthetic materials. Wide strips (binders) are used around the chest and abdomen. A popular form of binder is the many-tailed or scultetus binder. The sling has already been described.

There are many types of bandages which can be applied with a roll of gauze (Figs. 6, 7, 8). The *circular* or *spiral bandage*, as its name implies, is used to cover the sides of an extremity or finger. If the tip of the finger is to be covered or an amputation stump dressed, recurrent layers are first placed over the end and the dressing called a *recurrent bandage*. The *figure-of-eight* is a widely used type which consists of two crossed loops of gauze. When used to immobilize a joint—as the knee, elbow, or ankle—the loops are placed on either side of the joint. When the loops are passed around each shoulder, crossing between the scapulas, traction can be applied to the clavicles. This is a useful bandage for fractures of the clavicle. A *gauntlet bandage* is really a figure-of-eight in which one or more fingers are embraced in one loop and the wrist by the other, the bandage crossing over the dorsum of the hand. A *spica bandage* is applied in a manner similar to a plaster spica, as already described, but gauze alone is used.

Special bandages go by the names of their inventors. Thus *Barton* described a head bandage in which the roll of gauze is made to form three loops, one encircling the head longitudinally in front of the ears, the second horizontally just below the lip, including the chin and passing below the ear, and the third obliquely joining the first two and passing from the top of the head around the occiput. It is used in various head injuries. A *Velpeau bandage* serves to bind the arm to the chest and to elevate the arm. The hand is first placed on the opposite shoulder, the elbow resting against the chest wall. One turn of gauze passes around the shoulder and the flexed elbow, the other encircles the arm and chest. However, this dressing or bandage is so uncomfortable that it is now used only occasionally.

Heat and Cold. One must distinguish between the effects of heat and cold. The latter

The Barton bandage is also used for dressings about the head; it is a more extensive bandage since it passes beneath the jaw and around the occiput.

deals largely with environmental temperature which is known to influence the outcome of certain diseases, particularly burns, shock, and extensive infections. Fever, which is discussed separately, produces some of the effects of high environmental temperature.

GENERAL EFFECTS. Environmental temperature varies widely in different parts of the world and at different seasons. Much has been learned of the physiologic effects of environmental heat by observations made during fever therapy and of cold by the recent studies on hypothermia (30, 31).

Although the sensible and insensible loss of water and electrolyte is greatly increased by high temperatures, the humidity and the movement of air must also be mentioned as factors. Insensible loss of water by evaporation through the intact skin and in the expired air contains no salt, whereas sweating by actual secretion contains a variable amount of salt, increasing with the rate of secretion from a low level toward, but not equal to, the concentration of salt in the plasma. Workers in high ambient temperatures may lose a maximum of 2 liters in 1 hour, as much as 10 liters in 24 hours (32). Fever itself has a similar influence on water and electrolyte metabolism. These factors are of obvious importance in providing the proper intake of water and electrolyte, as discussed later.

THE LOCAL EFFECTS. The local physiologic effects of heat and cold have been studied widely; the details may be found in many publications. One might summarize these observations briefly by saying that heat, either local or general up to 40° C. (104° F.), increases local blood flow, exudation, and cellular activity, imparting a local sense of warmth. Above this point, injurious effects on the tissues begin and increase progressively. Increased tissue metabolism even below this level may prove harmful when the circulation cannot keep pace, as in peripheral arterial disease or in shock. Local cold in general has an opposite effect to that of heat; i.e., there is a sense of cold and a decrease in blood flow, exudation, and cellular activity. As temperature falls progressively, anesthesia replaces the sense of cold and becomes more

and more pronounced, becoming complete slightly above the freezing point of water. At a point slightly below freezing, cell metabolism ceases and the cell dies. However, single cells, if carried rapidly through the freezing point to extremely low temperatures, maintain their vital potential indefinitely. When brought back through the freezing point at any subsequent time, life is restored and normal activity resumed. In this way viruses, bacteria, and even spermatozoa may be preserved for years (33).

As the local temperature falls progressively, the color of the skin becomes either pale or cyanotic due to increasing vasoconstriction. As the freezing point of water is approached, this effect, however, may be intermittent, alternating with waves of active vasodilatation and increased blood flow as shown by a pink color of the skin. Below the freezing point the blood coagulates, whereupon all blood flow ceases. Under these conditions, irreversible changes take place followed by thrombosis and necrosis.

The local effects of heat and cold are usually superficial, limited to a few millimeters below the surface, but deeper penetration is sometimes possible. This is true of certain types of heat, such as the infrared ray, diathermy, and radiothermy. Cold on the other hand, unless excessive in degree, is usually superficial.

Therapy with Local Cold and Heat. The application of wet, cold sheets or immersion of the body in cold water is useful in reducing an abnormally high temperature, particularly in patients with thermic fever. An ice bag is of value to relieve pain and to limit or halt exudation. Its value in acute infections is disputed. The authors feel that cold is apt to be injurious in severe bacterial inflammation. Certainly, excessive cold is prone to damage delicate tissues and is poorly tolerated by the very old and young. Its anesthetic effect is responsible for the absence of any warning stimuli before such damage is done. Local cold finds its greatest value prophylactically when used early to minimize edema following simple sprains, and to alleviate discomfort when applied locally, especially over deep-seated lesions. Refrigeration for a gangrenous infected extremity may be indicated in preparation for amputation (Ch. 18).

The frequent use of the ice bag in intraperitoneal inflammation, including acute appendicitis, is not only based on misconceptions but may actually lead to danger. The claim that cold aborts the inflammation is based on fallacious reasoning, since cold penetrates but a few millimeters below the skin surface. Moreover, its reputed inhibitory effect on intestinal peristalsis has not been substantiated by careful observation. Indeed, it has been shown that external cold actually stimulates gastrointestinal activity; inhibition is produced by application of heat (34).

Heat is of value in a wide variety of surgical conditions. In the treatment of infections it has been all but abandoned because of the dramatic effects of chemotherapy. Induced elevation of body temperature (artificial fever) has an established use in a variety of diseases but is no longer utilized because of the effective use of antibiotics. Local heat is useful because it imparts a sense of warmth which is appreciated in many painful lesions. Its greatest value, however, is the promotion of hyperemia and blood flow, and exudation and cellular activity in inflammation, thus aiding in nature's defensive reactions. Wet heat in the form of soaks or wet dressings is used especially in open wounds (Fig. 9); it aids in promoting discharges and in mechanically loosening necrotic tissue. Wet dressings should rarely be used for more than 24 or 48 hours because they lead to maceration of tissue. Dry heat is applied by means of a hot-water bottle, poultices of various kinds (which are changed as frequently as they cool), electric bulbs or pads, and infrared lamps or diathermy.

Transfusion. Richard Lower is credited with carrying out, in 1665, the first successful blood transfusion in dogs. Two years later, lamb's blood was injected into the vein of a human being for the first time; the patient recovered but was observed to pass urine "as black as soot" soon after, obviously hemoglobinuria resulting from hemolysis. Fatalities followed similar experiences whereupon the procedure was prohibited by law. One hundred and fifty years passed before transfusions were given from human to human by an English obstetrician, James Blundell. Safe use of the procedure, however, awaited the discovery of the blood groups by Landsteiner

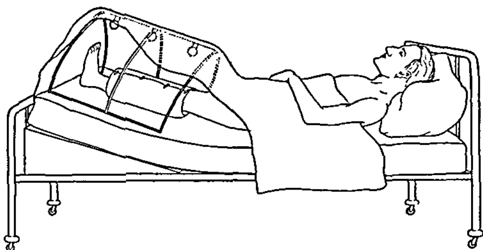

Fig. 9. A method of application of local heat to the lower leg by means of a cradle containing electric bulbs. Rest and elevation of the limb is also achieved.

(35) at the beginning of this century. For a long time thereafter, the inconvenience of giving blood directly from donor to recipient, often in the operating room, limited its application. With the introduction of citrate as an anticoagulant by Lewisohn (36) shortly before World War I, transfusions became so widely employed that blood banks are now maintained in practically all hospitals (37).

Transfusions are extensively used in surgical patients, most commonly to correct acute blood deficits. In general, transfusions are indicated: 1. To supply red cells after their loss by hemorrhage, in malnutrition, and in anemia from inadequate red blood cell formation, or abnormal loss through hemolysis. 2. To supply white blood cells in agranulocytosis, and platelets in thrombocytopenia; in both cases fresh blood must be used. 3. To supply one or more of the various protein fractions in the plasma, of which the most important are albumin, prothrombin, the unknown factor in hemophilia, and perhaps an antitryptic factor in acute pancreatitis.

Blood transfusions are most commonly and urgently employed for the correction of acute blood deficits produced by hemorrhage. The value of a transfusion after severe hemorrhage is greatly increased in direct proportion to the promptness with which it is injected after the loss. Speed and convenience have been greatly aided by blood banks, which have been set up in more and more hospitals during the past decade, and by the efforts of the American Red Cross. Blood banks, moreover, make it possible either to use whole blood or, by separating them, to use plasma and red cells separately. In the case of hemorrhage, whole blood is obviously the ideal replacement fluid, although plasma alone is preferable to red cells alone. However, injected plasma, because of its content of protein, maintains the normal colloidal osmotic pressure of the blood far better than saline. This, according to Starling's hypothesis, is the function upon which normal water interchange depends and is the property of blood which keeps it from escaping through the capillary wall thus maintaining normal blood volume without which circulation cannot be sustained. Plasma was used extensively as a whole blood substitute in battle casualties largely because of ease of storage and transportation, particularly when frozen or dried. It was later learned that such pooled plasma was a frequent cause of untoward reactions, particularly transmission of the virus of homologous serum jaundice. Indeed, much of the prepared plasma was eventually prohibited from clinical use and was made into various plasma protein fractions. Still later, safe plasma substitutes were developed, of which the most commonly used at the present time is a polysaccharide called Dextran (see page 255). The virus of homologous serum jaundice transmitted by plasma transfusions can be greatly attenuated or eliminated by

storage at room temperature (J. Garrott Allen).

During World War II, it was learned by actual experience that whole blood was so superior to plasma or plasma substitutes that the inconvenience of transporting whole blood and even the adverse changes during storage were accepted as minor disadvantages. Blood was either donated by civilians at home and sent by plane in a refrigerated condition to the far-flung theaters of war or obtained directly on the battlefield from convalescent soldiers or other personnel. Plasma, however, may be useful in many patients in shock who have not suffered loss of whole blood, but rather extracellular fluid containing varying amounts of plasma proteins. This is true in the case of severe hot-water burns, in peritonitis, and in extensive acute inflammation, for the lost fluid is essentially a 1 to 4 per cent plasma protein solution in physiologic saline. Ideal replacement therapy, therefore, consists not of saline alone, but of added plasma or some other colloidal solution. In such cases, hemoconcentration is often a guide to the amount of fluid needed for the correction of the deficit. On the other hand, whole blood is indicated for anemia which sometimes develops after several days in patients with burns. Many blood banks actually separate some of their whole blood into plasma and red cells, which permits one donation to serve more than one patient. It should be emphasized, however, that whole blood should be used when plasma is not available and vice versa.

For the prompt and often lasting correction of anemia of various types, whole blood transfusions (or packed red cells) are commonly used. A simple method for giving packed red cells is to store an inverted bottle of blood several hours, maintaining this position during transfusion until the cell-plasma interphase is reached. The red cells from 1 liter of blood will usually increase the red count by 500,000 to 800,000 cells per cubic millimeter, or the hematocrit by 5 to 8 per cent, unless there is further or continued loss of red cells. In acute hypoproteinemia occurring in conditions other than hemorrhage—as general peritonitis, intestinal obstruction, extensive tissue inflammation and exudation—whole blood and plasma are each effective. Here too, as in shock, the question of using whole blood or plasma depends upon what is lost and the relative concentration of the red cells.

In chronic anemia and hypoproteinemia of nutritional origin, whole blood and plasma are both useful and clinically valuable, particularly in preoperative preparation. They may even be needed when there is a normal concentration of hemoglobin and plasma proteins, provided the total blood volume is low. Blood volume measurements, however, require an exact technic which must be interpreted correctly. As the sole source of parenteral protein feeding, blood or plasma is inconvenient, expensive, and unphysiologic as compared with amino acid mixtures.

The technic of obtaining whole blood and the various precautions necessary for the establishment of a blood bank are now so well known that the details will not be described (Fig. 10).

The Hazards of Blood Transfusions. The dangers of blood transfusion must be emphasized (38), for with the development of blood banks has come a tremendous increase in the use of whole blood. Despite the most careful and meticulous technic, untoward reactions following transfusion cannot be entirely eliminated and, indeed, may reach an incidence of 3 per cent. Most of them, fortunately, are pyrogenic and of little consequence, but a few are due to incompatible blood and are serious. Moreover, under the best conditions, the procedure carries with it a certain mortality, though perhaps not more than one in 3,000 transfusions. The danger of reaction is greatly increased when multiple transfusions are indicated, in that each unit given must be compatible, not only with the patient's blood but with each unit given previously or subsequently. The possibility of transmitting the virus of homologous serum jaundice must also be recognized as a potential hazard.

For these and many other reasons, transfusions should be given only when definitely indicated and the amount limited to that actually needed. For example, transfusion is not necessary as routine during operation for a fall in blood pressure due to neurogenic factors or to the position of the patient. Another

Fig. 10. A method for obtaining blood from donor. Note that this is a closed system. The airtight flask contains the proper amount of citrate solution (50 ml. of 2.5 per cent for 500 ml. of blood) and is sealed with a partial vacuum so that the flow of blood is automatic and does not depend on gravity or the positive venous pressure to fill the bottle.

example, blood transfusion should not be given before operation merely because the hemoglobin report is a little low in a patient in good general condition who has had no evident blood loss. In such a case, repeating the laboratory test may be a much easier way of correcting a suspected deficit. Still another example is the needless use of blood to replace moderate loss during operation, in patients whose normal regeneration processes can be counted on to correct the deficiency during the postoperative period. This is particularly true in *radical resection of the breast* in a healthy woman. In many cases more blood is used than is actually necessary. The amount of blood transfused should be judged by the amount that has been lost. If it is clear that only 1 liter has been lost, 2 or 3 liters should not be given just because the blood pressure has not been fully restored. The surgeon and the anesthesiologist, in such a case, must look for other causes for hypotension and control the almost automatic impulse to give more and more blood. The danger of excessive transfusions in producing myocardial imbalance has been well documented by Holden and associates (39). Although it is also known that the mortality rate is high in patients with myocardial disease having major operations, it will be much higher if blood in proper amounts is not given (40).

Serious untoward reactions due to incompatible blood are usually hemolytic and, in an unanesthetized patient, are ushered in by the almost immediate appearance of profound dyspnea, cyanosis accompanied by smothering sensations, and severe pain in the chest or back. Should any of these manifestations *occur during the beginning of the transfusion*, the procedure must, of course, be stopped at once. In some cases, chills and fever occur, followed by acute renal shutdown (Fig. 11). Death may result immediately or in several hours, accompanied by shock, or days later by uremia. If there is any question as to a reaction, hemolysis should be suspected and a specimen of blood spun down and examined for hemoglobinemia. The urine should also be examined for hemoglobinuria. Later, hemolysis is revealed by the development of jaundice. An untoward reaction during operation produces fewer but more serious mani-

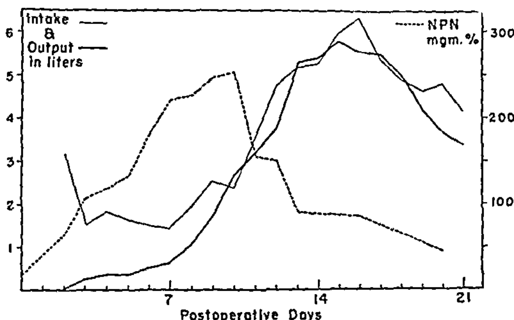

Fig. 11. Postoperative anuria due to transfusion reaction. Note the steady increase in the plasma nonprotein nitrogen and its fall only after diuresis had reached and exceeded 3 liters of urine a day. The daily fluid intake was kept under 2 liters during the oliguric phase, i.e., until about the seventh postoperative day, when it was increased parallel with the increasing diuresis. Note that 6 liters of urine was excreted on the sixteenth day. This large output was necessary to excrete all the accumulated nitrogenous waste products. Not shown is a progressive rise and fall in plasma phosphate which paralleled the nonprotein nitrogen. The plasma potassium rose to 7 mEq. per liter (27 mg. per cent) on the ninth day, although the electrocardiogram showed no change, and promptly returned to the normal of 4 mEq. (15 mg.) a week later. The plasma chloride was low (80 mEq. per liter or 284 mg. per cent) on the sixth day and returned to normal slowly by the sixteenth day, long after the diuresis was established. The plasma sodium level fell (to 125 mEq. per liter) with the chloride but returned to normal much more rapidly. Restoration of Na^+ and Cl^- was aided by increasing the salt intake during the period of recovery. In this case there was no change in the plasma bicarbonate content.

The patient made an uneventful recovery; two months later his kidney function was studied and found to be normal. (From Elman, R. Surgical Care, Appleton-Century-Crofts.)

festations. Failure of the blood pressure to respond to the transfusion, a dusky color of the skin, and an increase in oozing from cut tissues everywhere are usually present. Diagnosis can be confirmed by finding hemoglobin in the plasma or in the urine. Increased oozing may also occur after massive transfusion of compatible blood. Since platelets disappear from stored blood in a matter of days, this platelet deficiency may be responsible for the bleeding which can be corrected by substituting fresh for stored blood. Other causes for such oozing may be an increase in fibrinolysin, more recently called plasmin, a proteolytic ferment which dissolves blood clots; it is treated by administration of fibrinogen. Profuse bleeding may also be caused by hyperheparinemia. The etiology of this condition is not clear insofar as there is no agreement as to whether or not the causative agent is really heparin but a heparinlike substance. However, the condition may be treated effectively by protamine or toluidine blue.

Other serious reactions may be due to the accumulation of unmetabolized citrate, to contaminated blood, to allergic reactions which may even result in anaphylactic shock, to circulatory overloading, and to air embolism from careless use of positive air pressure. Homologous serum hepatitis may occur later; hemosiderosis, still later. Less severe untoward reactions after transfusion are usually pyrogenic and in general are not serious.

Mention should be made of the influence of the Rh factor (41). Rh refers to an antigen present in the blood of most humans; it is so called because it also is found in the red cells of the monkey (*Macaca rhesus*). Reactions due to the Rh factor may occur because a few individuals do not have this antigen, i.e., their

blood is Rh-negative. Should they receive blood from an Rh-positive donor they may become sensitized so that subsequent transfusions with Rh-positive blood may produce a severe hemolytic reaction similar to that observed with incompatible blood. Inasmuch as it is possible to test for the presence or absence of the Rh factor, it is obvious that any patient with Rh-negative blood will require the selection of an appropriate donor who also has Rh-negative blood. Untoward reactions have also been ascribed to the added citrate, especially when large amounts of blood have been given (42). A complete discussion of the various dangers will be found in texts devoted to the details of transfusions.

The treatment of severe transfusion reactions depends on the cause. An injection of 10 ml. of a 10 per cent calcium gluconate solution has been recommended, especially for hypotension; it presumably reacts by removing excess ionized citrate (43). Acute anemia may call for the transfusion of washed, fresh red cells. Other therapy includes antibiotics for contaminated blood; cortisone for severe, benadryl for less severe, allergic reactions; venesection for overloading.

The usual amount of blood which can be safely drawn from the average adult donor without symptoms of hypovolemia is 500 ml. In most cases much larger amounts are required, which means the use of several donors. On the other hand, in babies and children, the amount may be much less than 500 ml.

Refusion is another term for *autotransfusion.* When severe intraabdominal hemorrhage has occurred, from trauma either before operation or during operation, it is sometimes possible to save much of the spilled blood and inject it into the patient's vein. When a gunshot or stab wound has severed a large vessel and also perforated a viscus so that the blood is mixed with urine or intestinal contents, refusion should not be done except in a dire emergency. However, years ago, before blood was so readily available from a blood bank, such contaminated blood was used occasionally, and without any untoward results. In refusion, the spilled blood is collected in a basin containing sufficient sodium citrate to prevent clotting. Suction has the disadvantage of breaking up the red cells. The blood is then strained through several layers of gauze and given intravenously. Isotonic saline and glucose may be added to augment the fluids. Because of the availability of blood banks and various blood substitutes, refusion is seldom necessary at the present time, but more use should be made of uncontaminated blood when found free in the peritoneal or thoracic cavity at the time of operation for injury. The use of blood substitutes is discussed elsewhere (p. 255).

Resuscitation. Resuscitation, which really means the restoration of life, may be necessary in case of sudden respiratory failure (asphyxia) or circulatory failure (cardiac arrest). These often occur simultaneously or follow each other within a matter of seconds. Speed is the essence of resuscitation which can be successful only if carried out within a very few minutes and if there is no irremediable organic basis for the accident. Various methods of resuscitation are discussed by Saklad (44). Respiratory and cardiac emergencies are also discussed in Chapter 11.

Artificial respiration is indicated when breathing stops suddenly, whether from drowning or other causes. Treatment for cardiac arrest when present must be carried out simultaneously. Regular inflation and deflation of the lungs are obviously required so that interchange between the lungs and outside air may occur. The upper airway, of course, must be patent and to insure this, the tongue and jaw must often be drawn forward in order to prevent obstruction of the pharynx.

Interchange is brought about by one of two general methods. 1. Air is forced intermittently into the lungs, allowing the elasticity of the chest wall to expel it on the release of pressure. This is the principle involved in mouth-to-mouth insufflation or with the bag of a gas anesthesia machine. The latter method is a simpler method, but the equipment will rarely be available except for emergencies occurring in the operating room. Accordingly, the mouth-to-mouth method is being recommended for use outside the operating room, particularly since it is so effective (Gordon et al.). (Fig. 12.) 2. Air is forced out by external compression of the chest wall, thus allowing air to enter on release of pres-

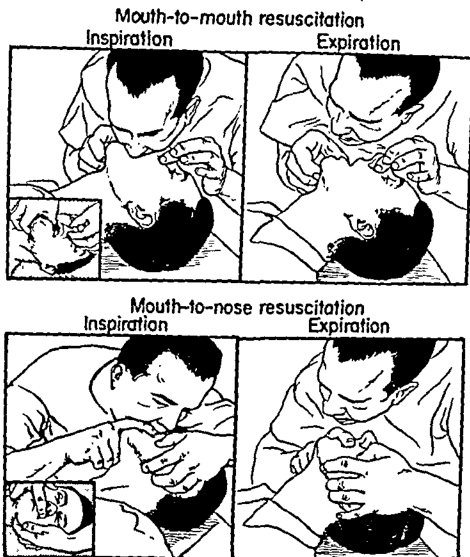

Fig. 12. Technics for mouth-to-mouth and mouth-to-nose resuscitation. (From Gordon et al., J.A.M.A.)

sure from elastic recoil of the thoracic cage. This principle can be applied to the patient in both the supine (face up) and prone (face down) positions. In the former, the greatest expansion of the chest is produced by first extending the arms overhead. Expiration is then effected by bringing the arms down and compressing them against the chest. When possible, however, the prone position as in the Nielsen method (Fig. 13) is preferable, inasmuch as it allows the tongue to drop forward, thus keeping the air passage open. This position also aids in the expulsion of vomitus which might otherwise be aspirated, especially by a comatose patient whose tongue would otherwise fall back, producing obstruction. The prone position also tends to aid the drainage of water from the lungs in drowning, although there is now evidence that on most occasions little or no water is present in the pulmonary tree of the drowned person.

When an organic obstruction is present, artificial respiration is obviously useless. Such an obstruction, usually at the larynx, is first manifested by the patient's extreme restlessness. The diagnosis becomes more obvious later because of the forceful attempts on the part of the patient to breathe, during which time he uses all of the accessory muscles of respiration, including the neck muscles. In such an event it is mandatory to resort to tracheotomy or laryngeal intubation as an emergency. The use of drugs such as caffeine and lobelin is of no proved value, although there is no harm in their use, especially the former. There is no evidence that they can

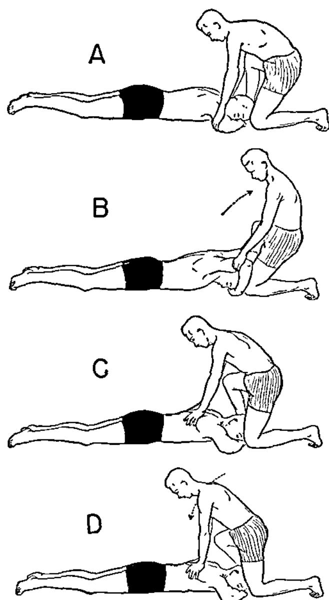

Fig. 13. The Nielson arm-lift back-pressure method of resuscitation. The Nielson method of artificial respiration as illustrated above is about equal in efficiency to the back-pressure hip-lift method but is easier to execute. The mouth-to-mouth method is equally effective and actually has certain advantages over this method. (From Gordon et al., J.A.M.A.)

start respirations which have ceased. When respirations are weak and shallow, the use of carbon dioxide as a respiratory stimulant is advisable, particularly for shallow postanesthetic breathing and in carbon monoxide poisoning. It is given mixed with a high concentration of oxygen.

Artificial respiration, when successful, should be followed in a few minutes by spontaneous breathing. If artificial respiration is required for several hours, the Eve method is recommended but requires an elaborate tilting device to permit alternate change from the head down to head up position. In this way, the abdominal contents pull and push on the diaphragm and produce respiratory exchange. The mouth-to-mouth and Nielsen methods are simpler and achieve the same result. The electrophrenic method of Sarnoff (45) is ingenious, simple, and apparently quite effective. If artificial respiration is required for long periods because of muscular

paralysis, as in acute poliomyelitis, various types of respirators are available.

After sudden *cardiac arrest*, the simplest procedure, which is occasionally effective, is thumping the precordium, combined with vigorous artificial respiration, since asphyxia nearly always accompanies cardiac arrest. *Puncture of the heart* with injection of adrenalin has apparently been responsible for saving many lives, but *manual massage of the heart* is the most successful method of starting the stopped heart and can readily be done during the course of an abdominal operation through the diaphragm or, more effectively, by means of an intercostal incision made over the precordium. Massage should be slow, rhythmic, and gentle; electric shock with especially prepared electrodes is indicated in the presence of ventricular fibrillation. Artificial pacemakers may also be of value. The incidence of cardiac arrest during operation, however, can be greatly reduced by meticulous and constant care during the anesthesia, with special attention to avoid hypoxia. These and other features of resuscitation more directly connected with anesthetic complications are discussed in Chapter 11, on anesthesia.

Whatever is done in the case of cardiac arrest must be done within a matter of four minutes, since cardiac arrest for longer periods produces permanent cerebral damage and may be incompatible with life. On the other hand, the decision to open the chest and massage the heart requires critical judgment.

The Hollow Needle. The origin of the hollow needle is clouded in the dim mists of antiquity, although it is probable that goose quills were used by savages and bronze tubes by the ancients as trocars for the evacuation of fluids in the chest or abdomen. For example, Hippocrates employed a small tube in empyema and mentioned beveling its edge, although an incision was first made between the ribs. Celsus wrote of a cannula for draining ascitic fluid. The syringe itself is of more recent origin. Abulcasis, an Arabian physician about A.D. 1000, is credited with the first description of a "cannula" which contained a plunger of copper armed with cotton and was used to irrigate the external auditory canal. A goose quill attached to a pig's bladder was used in 1658 to inject medicants into the vein of a dog for the first time by no less a person than Sir Christopher Wren, the famous English architect and astronomer whose greatest fame is enshrined in St. Paul's Cathedral, in London, which he designed. The modern hypodermic needle to introduce drugs is said to have been developed only as recently as 1834 by a Dr. Alexander Wood of Edinburgh. In its present form the needle is made of stainless steel with or without a stilet and with sharp, beveled edges to permit easy introduction. It is also made in a great variety of sizes for various purposes.

The hollow needle may be used either to introduce or withdraw fluid or air. The injection of fluid may be intradermal, subcutaneous, intramuscular, intravascular (Fig. 14), intraspinal, or into serous cavities, joints, or other spaces. Withdrawal of fluid is spoken of as aspiration and sometimes as tapping. Needles are used to aspirate fluid from the peritoneal cavity, spinal subarachnoid space, the cerebral ventricles, cisterna magna, pleural space, joints, and from abscesses or cysts. In solid tumors of doubtful nature, large needles are often useful in actually removing a core of tissue for microscopic examination and diagnosis. This procedure, however, must be used with caution when malignant tumors are suspected because of the danger of local spread.

1. *Intradermal injections* are made with a fine hypodermic needle to introduce novocain for local anesthesia, or such biological materials as tuberculin or scarlet fever antigen, for diagnostic purposes. A raised wheal is formed when the material is injected into the derma.

2. *Subcutaneous injections* with small hypodermic needles are made for the administration of most drugs (morphine, atropine, and so forth). When large amounts of fluid (saline) are injected, a larger and longer needle is employed. This procedure is called hypodermoclysis and was formerly a popular, though now uncommon, method of giving parenteral fluids.

Hypodermoclysis has obvious advantages over intravenous infusions, which will be discussed separately. There is no problem of venous puncture and no danger of pyrogenic reaction or thrombophlebitis. On the other hand, hypodermoclysis may be painful if

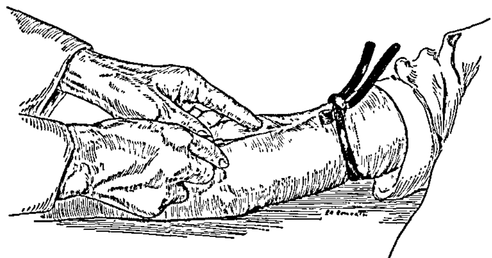

Fig. 14. The proper method of performing a venipuncture for the withdrawal of blood or for intravenous medication. The tourniquet is placed to bring the veins into bold relief; it is removed as soon as the vein is entered, as indicated by the free flow of blood into the syringe.

given too rapidly, may introduce infection if not given aseptically, and has other more specific limitations which are discussed below. Common sites for subcutaneous infusion are the axilla, which contains a good deal of loose areolar tissue and is richly supplied with lymphatics for rapid absorption, the inner side of the upper thigh, the lower abdomen, and the groin. Subfascial and intramuscular infusions have also been recommended, but are more apt to be painful and are now seldom employed. Hyaluronidase, as a spreading agent, is sometimes added and does diffuse the injected fluid over a wider area of the subcutaneous space. This tends to prevent the pain due to rapid accumulation of fluid at one site, thus shortening the total period of injection. Saline solutions may, perhaps, be absorbed more rapidly with hyaluronidase, but other solutions such as glucose are not (see below).

The absorption of isotonic saline solution is now known to occur progressively from the time the infusion is started. Solutions containing glucose or amino acids, though isotonic with the body fluids, behave quite differently. Both experimental and clinical studies have shown (46) that equilibrium between such solutions and the extracellular fluid must first be established before absorption begins. During this process, water and salt move into the subcutaneous space containing the glucose, depleting to that extent the extracellular fluid. The reasons are as follows: First of all, glucose and amino acids are larger molecules and, hence, move much more slowly than do sodium and chloride ions; and second, unlike sodium chloride, the concentration of glucose, even when isotonic (5 per cent), is 50 times its concentration in the extracellular fluid. Thus, the period of time required for equilibrium and total absorption may be prolonged from about seven hours, which is the average period in the case of isotonic saline, to 24 hours or more. These factors may not be significant in patients with a normal circulation and satisfactory water and electrolyte balance. In ill persons, however, the situation may be quite different in that the temporary withdrawal of water and salt into the subcutaneous space may lead to peripheral circulatory impairment.

3. *Intramuscular injections* are absorbed more rapidly than those into subcutaneous tissue, but may be used only when the amount of fluid is small (up to 5 ml.). The deltoid and gluteal muscles are the usual sites, care being taken to avoid nerves and large vessels.

4. The *intravascular route* may be intravenous or intraarterial. *Venipuncture* is used for the aspiration of blood as well as for the injection of fluids directly into the blood stream; it must be done with a fairly large needle for the former, a smaller one, for the

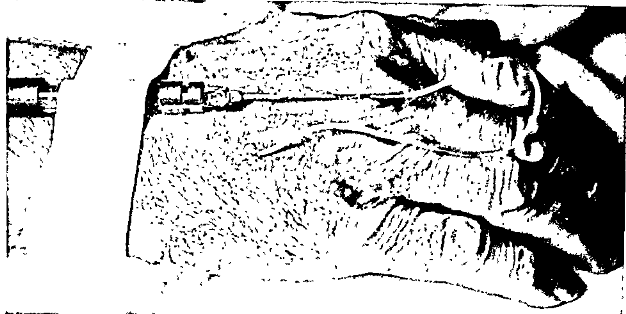

Fig. 15. Continuous venoclysis. The patient was a 75-year-old salesman. Following a sudden attack of abdominal pain, he was explored, and a foot long segment of gangrenous bowel caused by a localized mesenteric thrombosis was resected and an end-to-end anastomosis performed. While he was still in the operating room under anesthesia, the tiny catheter was inserted into the vein through a needle, which was then withdrawn. Two liters of Amigen and glucose were infused by continuous drip every 24 hours. The rate of flow was controlled by adequate nursing care. The photograph was taken four days later, just before the tube was removed and after oral feeding was started. Ambulatory from the night of operation, the patient was also able to use both arms without difficulty. Recovery was uneventful.

latter. For aspiration of blood, the two veins at the fold of the elbow in the antecubital space are commonly employed, although either the femoral or jugular vein and, in infants, the superior sagittal sinus, may be the only ones through which blood can be obtained.

For intravenous infusion, small veins may be used, *including those over the forearm, the* wrists, the dorsum of the hand (Fig. 15) and about the ankle. One of the problems of intravenous infusion, particularly when used for days and weeks, is the thrombosis of successive veins, making them useless for further infusion. These thromboses are significant, *however, only when they produce systemic* manifestations such as chills and fever. Of the many factors involved in thrombosis, the following may be specifically mentioned: (*a*) *Speed.* The faster the infusion is, the greater the likelihood of thrombosis. For example, even large veins can be quickly obliterated with *1 liter of 10 per cent glucose given* over the course of half an hour or less, *whereas* no change will follow the same infusion given during one or two hours. (*b*) *Tonicity.* Hypertonic solutions such as 20 per cent glucose, particularly when given rapidly and in a small vein, are much more apt to produce thrombosis than isotonic 5 per cent glucose solutions. (*c*) *Reaction.* Veins are much more readily irritated during infusions of acid or alkaline solutions. (*d*) *The relative lumen of vein and needle.* Any needle *which occupies the entire lumen of the vein* is much more likely to produce thrombosis than a needle small enough to permit the flow of blood around it. It is probable that small hypodermic needles could be used more frequently, provided that the rate of delivery is increased sufficiently by the controlled use of *positive pressure.*

Continuous venoclysis with tiny plastic catheters has been recommended and fairly widely used (Fig. 15). In large veins, these catheters may be introduced through the lumen of the needle used for venipuncture, after which the needle is removed. In smaller *or deeper vessels, it is necessary* to cut down on the vein and tie the catheter in place. In either case, constant supervision is required to regulate the rate of flow. This method may,

however, be used intermittently by filling the tube with heparin solution in the intervals between infusions. Patients appreciate infusion through such a plastic catheter for it permits free movement of the part and, of course, eliminates repeated venipunctures. Slow infusion also improves the utilization of glucose and amino acids (47). The disadvantages are due to thrombosis, which can be minimized by observing the point of entrance of the catheter through the skin two or three times a day and removing it at the first sign of redness or local inflammation. Otherwise, thrombosis will be evident only when the patient complains of pain along the course of the vein or has unexplained fever; occasionally chills occur with local pain and redness over the vein. Venoclysis through one vein is possible for three or four days on the average, although sometimes for a week or more. After this time, of course, the catheter should be removed. A second vein then can be used for an additional period. Meticulous aseptic preparation of the skin at the site of the injection, or "cut-down," and careful cleansing of the catheter tend to prolong the time each vein can be used safely. In desperately ill patients, continuous intravenous infusion for longer periods of time may be so important as to justify inserting the catheter into the saphenous or femoral vein and passing it up into the inferior vena cava or into an antecubital vein, passing it down into the superior vena cava. Under these conditions, thrombosis is much less likely to occur and the infusion may be continued for much longer periods of time. The intrasternal route has also been used. Even the corpora cavernosa of the penis has been utilized for intravenous infusion.

Intraarterial puncture is now frequently utilized, especially for diagnostic arteriography.

5. The *intraspinal* (lumbar subarachnoid) space is often entered to obtain spinal fluid for diagnosis. Spinal puncture is also used to introduce anesthetic agents for spinal anesthesia, air (or often contrast media) for diagnosis by x-ray, and antibiotics in meningitis. Suboccipital (cisterna) puncture has also been used. The epidural space may be entered at the sacral notch or above to introduce anesthetic drugs for the production of regional (e.g., sacral or saddle) anesthesia.

6. *Peritoneal puncture* to obtain fluid for diagnostic purposes in obscure abdominal disease is being used more and more despite the apparently slight danger of perforating the lumen of the small intestine. As a means of introducing parenteral fluids, it is rarely utilized except in remote areas where other methods are not available. The hazard of intraperitoneal infusion arises not so much because of the danger of perforating the intestine, but because even isotonic saline solutions tend to produce a mild type of plastic aseptic peritonitis.

Paracentesis abdominis (peritoneal tap) is indicated to remove ascitic fluid in tuberculosis, peritoneal carcinomatosis, cirrhosis of the liver, or heart disease. A large, hollow needle (trocar) is used with a stilet in its lumen. The point of entrance is best prepared by making a tiny incision in the skin and fascia with a sharp, pointed blade.

The pleural space is entered for aspiration of fluid for diagnosis and treatment (paracentesis thoracis) and for the aspiration or injection of air (artificial pneumothorax).

The Catheter. A catheter is a tube, ordinarily flexible, which may be introduced into cavities for the purpose of draining or instilling fluid. Catheters used to be made only of rubber or of woven fabric. The newer plastics now are displacing rubber. For one thing, they are less irritating to tissue and to mucous membranes. They can be made of various plastics, each possessing specific and predictable properties such as transparency, consistency, stiffness, and maleability.

1. The *stomach tube,* for introducing fluid (gavage) or for removing fluids (lavage), is ordinarily used in one of two sizes. The large, more or less rigid stomach tube (No. 286) can be made to enter the stomach rapidly and is, therefore, of special value when rapid evacuation and irrigation of the stomach are necessary, notably after the taking of poison. A large tube also enables removal of thick or tenacious material in some cases of pyloric obstruction. The large tube may also be indicated in patients including the unconscious, who are unable or unwilling to swallow. It, of course, must not be used in those suspected of having ulcerated lesions, varices, or in those with heart disease.

In any case, the large tube is utilized temporarily and removed as soon as its purpose has been fulfilled.

The small tube (No. 16F) is used much more frequently. It is available in several forms, first as a simple catheter, with or without a metal tip, for continuous aspiration or feeding. For the latter purpose, tiny plastic tubes are now being used more widely. Another type of small tube is equipped with a balloon at the end, containing mercury, which enables the tube to pass more readily past the pylorus into the duodenum and small intestine for purposes of intestinal decompression. Still another type has two lumens, one for inflating the terminal balloon, the other for evacuation of intestinal contents.

2. The *rectal tube* is of the same caliber as the large stomach tube, but it is much shorter and is used to permit evacuation of gas (made difficult or impossible by anal spasm), to introduce solutions for absorption, to stimulate bowel movements, or to cleanse the colon with enemas. Rectal tubes do not pass above the rectum unless introduced into the sigmoid by a long proctoscope. Fluid in small amounts, about 200 to 300 ml., fills merely the rectum. In order to reach the cecum much larger amounts, several liters, are necessary. Perforation of the colon by introducing large volumes of fluid under pressure is an obvious mechanical danger which can be avoided by careful administration at low pressures.

To stimulate defecation, various solutions have been used; the procedure is classified as a low or high enema, depending upon the amount of fluid utilized. Ordinarily a small or low enema is adequate, for it is necessary merely to chemically stimulate the rectal mucosa. Of the many kinds of enemas, the following are probably the most common.

(*a*) *Soap suds* (ss) enema, consists of 1 liter (34 ounces) of warm tap water to which thickened soap has been added to produce a light suds. It is given slowly and the administration stopped at the first evidence of discomfort. If defecation does not follow, and the enema is retained, it must be siphoned off.

(*b*) *Magnesium sulfate, glycerine, and water* (mg&w) enema is smaller in volume but more irritating to the mucosa and, hence, often more efficient than an ss enema. Its composition ordinarily is as follows: 60 ml. of a 50 per cent solution of magnesium sulfate, 60 ml. of glycerine, and 60 ml. of water. A small glycerine suppository is simpler and, in about half the cases, just as effective as an enema.

(*c*) *Oil enema* consists of 100 to 200 ml. (3.5 to 7 ounces) of warm oil which is retained for several hours, presumably to soften a mass of impacted feces. It is then followed by an ordinary ss or mg&w enema. When the fecal impaction is hard and extensive, which is more common in children and in older individuals, mechanical removal must be employed, particularly when enemas fail.

(*d*) *Cleansing enemas* in large volume are often effective in removing fecal material from the entire colon in preparation for operation on the colon, particularly in children with megacolon. Tap water is potentially dangerous in this disease because enough absorption may occur to produce "water intoxication" which unfortunately has proved fatal in a few cases, especially when unrecognized and untreated by administration of salt solution. Isotonic saline should obviously replace tap water to prevent such a complication.

(*e*) *Other enemas*, such as those of milk and molasses or oxgall solutions, have the sanction of long tradition and are still used by a few older surgeons, although most of them are of historic rather than of practical interest.

3. *Catheterization* of the bladder is necessary in many conditions, such as prostatic obstruction and postoperative retention. In spite of aseptic precautions there is always the hazard of introducing bacteria and producing cystitis, a hazard which has been increased by the large number of antibiotic-resistant staphylococci now frequent in many hospitals. Careful technic must, therefore, be meticulously observed in all cases in order to reduce this danger to a minimum. The technic is described in Chapter 41.

SURGICAL CONVALESCENCE

Preoperative Preparation
Postoperative Care

Convalescence, literally, *means growing* strong and, traditionally, has referred to the period following the ravages of disease, when the patient is restored to normal health. This concept accepted the destructive aftermath of disease, often called in surgery "the catabolic phase" of injury (Ch. 12), as inevitable, to be allowed to run its course even though it left the patient weak, wasted, and wobbly. The next step, therefore, was called the period of convalescence, which was often so long that convalescent homes were recommended and, at one time, really needed and proved to be popular. In surgery, it was considered that the effects of operation—even of such relatively simple ones as herniotomy—took a convalescence of three weeks in the hospital, *followed by three weeks at home.*

The contrast with the present attitude is striking, as shown dramatically in the time allotted to convalescence. Instead of six weeks, it is common for patients to leave the hospital in 10 days or even less after a gastrectomy, and to return to work (if they wish) in two weeks. This change has come about for many reasons, basically because it was soon realized that the reparative process could start with the first day of injury, just as the aging process is said to start at birth. This idea of a dynamic equilibrium between injury and repair, catabolism and anabolism, atrophy and growth, has stimulated therapeutic efforts to minimize the former and to improve on the latter, usually at the same time. In this chapter, a few of the factors involved will be discussed, particularly in terms of preoperative preparation and postoperative care. For details the reader is referred to a number of publications specifically devoted to the details of preoperative and postoperative care (1, 2, 3, 4, 5).

PREOPERATIVE PREPARATION

An operation should not be undertaken lightly, nor will it achieve its maximum benefits unless adequate attention is given to preoperative planning, whether the preparation demands days or weeks, or must be completed in minutes or hours. In this section three elements of preparation will be discussed; first, the mental state of the patient, called the *psychogenic factors,* which unfortunately are often neglected. Next and even more important are the *diagnostic requirements,* because these deal not only with the indications and need for operation but also for the evaluation of the risk. Despite the relative safety of operation—thanks to the tremendous advances in anesthesia, including supportive therapy—the surgeon must always reckon with its risk, which is dependent largely upon the physical state of the patient as revealed by the diagnostic data. Third are listed the *specific preoperative procedures,* including particularly the correction of various deficits.

Psychogenic Factors. Often overlooked as unimportant, psychogenic factors may actually play a decisive role in the course of disease (6). The mental state of any patient is inevitably influenced from the very onset of his affliction and is affected favorably or unfavorably by every contact with his physician and, later with other personnel, should he enter the hospital. Once an operation has been definitely decided upon, the importance of psychogenic factors increases, particularly the reaction of the patient to the proposed surgical procedure, his ideas of what it means,

the consequences thereof, and especially the fear of anesthesia. These factors may exert either a favorable or a harmful influence upon convalescence, depending to a considerable extent upon the efforts of the surgeon in charge. To overlook the influence of mind over matter (and vice versa), or to leave it to chance, is to neglect an important part of the clinical picture and to miss significant therapeutic possibilities. Most of the unfavorable psychic influences are based on ignorance, fear, and apprehension, due somewhat to an accumulated background of misinformation, sometimes transmitted by word of mouth, or to misinterpretation of chance remarks overheard after entry into the hospital. Much of the influence of psychogenic factors has to do with the morale of the patient and with boredom, particularly when the surgical disease requires long periods of hospitalization and repeated operations.

An important step in the psychologic preparation of the patient for operation is an unhurried discussion by the surgeon in charge, for he has the opportunity to banish fear and apprehension based upon ignorance. In such an interview, the patient's natural curiosity about his disease should be satisfied, including a discussion of the plans for diagnosis and treatment and the objective to be reached. The time required need not be long, and the details may be few or many, depending upon the individual case and the intelligence of the patient. The surgeon should discuss the diagnosis and prognosis frankly, even when dealing with carcinoma. While surgeons may disagree on this point, the authors feel that, with few exceptions, the diagnosis (and prognosis even if bad) should not be withheld. It is true that many patients become depressed and lose all hope when they learn they have cancer. Because they will learn the truth sooner or later and often with exaggerated prognostic implications, it is far wiser for the surgeon himself to be the source of this information. Such candor not only prevents deception but also actually encourages confidence in his doctor by the patient. It is often not so much that it is the truth, but the manner in which the truth is revealed, that hurts. Hope is the greatest agent we have in the face of serious and ultimately fatal disease, and it should be exploited to the fullest, together with other needed therapy. However, on occasion, it would be unwise to tell the patient he has cancer, because his emotional stability may not be sufficient to tolerate the news. The physician must decide which patients are of this type. The patient may be told he has a growth or tumor which must be or has been removed. Close cooperation by discussion with other members of the family is important under all circumstances and should not be neglected.

A second consideration has to do with courteous and sympathetic care, quiet and restful surroundings, and prompt and efficient attention to a routine, all of which serves, almost at once, to put the patient's mind at rest and to engender a sense of security which constitutes mental rest. Cheerfulness and reassurance on the part of the nursing and intern staff will achieve the same end result. This attitude should be continued during the entire stay of the patient, but it is particularly important just before and after operation. No plan of preoperative preparation can be called adequate unless the patient is free of apprehension, is mentally composed, and has perfect faith in his surgeon as well as in others concerned with his care. Psychogenic factors will prove beneficial rather than harmful if the surgeon in charge evokes the utmost in teamwork by all of those attending the patient.

Psychogenic factors before operation may also play an important part in arriving at a correct diagnosis inasmuch as certain patients may exhibit acute symptoms, particularly abdominal pain, which may be produced by functional disorders such as spasm, rather than acute infection, e.g., appendicitis. It is now well known that a certain type of patient may present symptoms suggesting acute abdominal disease which actually are of psychic origin. Most wise and honest surgeons are able to identify these patients, but in some cases the problem may tax the ingenuity of the most experienced practitioner.

Diagnostic Requirements. The minimum and mandatory diagnostic procedure before any operation in a hospital includes a routine history and physical examination (including blood pressure measurements), a laboratory urinalysis, and a red and white cell count, including a differential. This alone, especially in

emergency operations on patients in previous good health, will tend to avoid unnecessary operations and prevent the tragedy of an ill-advised procedure by the detection of physical defects which may contraindicate it or demand special preparation. When the patient is in poor general condition, the history may reveal the nature of the tissue and fluid deficits, or special blood chemical analyses may be indicated. The influence of psychogenic factors in the diagnosis, as just mentioned, is of obvious significance.

Diagnosis, while the responsibility of the surgeon in charge, is often affected decisively by the intern's routine observations. His history and physical and laboratory examinations may reveal details of significance bearing on the case. Thus an early pregnancy may be detected in a patient about to have an appendectomy for supposed subacute appendicitis. Finding amebas in the stool may contraindicate an immediate laparotomy for an acute surgical condition of the abdomen; the early skin lesion of herpes zoster may be noted in a patient with an erroneous diagnosis of acute cholecystitis; neurological changes may indicate that a gastric (tabetic) crisis rather than a perforated ulcer is the disease present. The intern may likewise detect a sore throat, a furuncle, or other beginning infection near the operative field, each of which may justify postponement of an operation of choice. He may even find evidence of *coexistent disease (see below) including* such lesions as a carcinomatous lump in the breast of which the patient (and her physician) is completely unaware.

Diagnostic procedures are especially decisive in estimating surgical risk and as a guide for the correction of deficits as discussed below. Surgical risk, as revealed by the diagnostic findings, should permit the surgeon to evaluate fairly accurately the *physical state of the patient.* Unfortunately, errors in determination of operability are made too frequently, even by good surgeons. The best operation in the world is no good if it kills the patient. Determination of operability is difficult because there are no mathematical means of determining it. The surgeon must *look for* complications and deficiencies, and weigh their deleterious effects against the operative load planned *for the* patient. Important among these are malnutrition, hepatic insufficiency, cardiac disease, hypertension, and nephritis. Special attention must be given to operations in aged people (6) because the presence of complications or decrements of any type will increase the *expected mortality* rate; in the absence of preoperative and postoperative complications, aged patients will tolerate operations very well. We must treat these complications and deficiencies preoperatively, correcting as many of them as we can. To eliminate or minimize the danger of a fatality, it may be necessary to postpone operation for additional treatment or to modify the type of operation to be carried out. Accordingly, we must increase our efforts to improve the accuracy of our estimation of operability.

Pregnancy, although not classified as a disease, does affect both surgical diagnosis and preoperative preparation. The influence of a coexisting pregnancy on surgical disease of various kinds is discussed in other parts of the text.

Special Preoperative Procedures. Preoperative procedures may be simple or complicated, depending somewhat upon the urgency and the risk of the operation, as discussed above. In the following discussion, three groups of preparatory measures and one transition stage are considered, not in great detail inasmuch as further information can be found in other sources already mentioned.

1. *Special procedures* depend upon the type of operation to be carried out and will be treated in the discussion of the regions involved. For example, gastric lavage is essential before gastric resection whenever there has been excessive gastric retention due to pyloric obstruction. This permits edema and inflammation of the stomach walls to subside. Cleansing enemas are necessary before operation on the colon. Refrigeration of a gangrenous infected extremity associated with severe systemic signs of toxemia, especially in the presence of diabetes, will greatly reduce the mortality due to amputation. These special procedures are carried out while various nutritional and other deficits are being corrected.

2. *Correction of deficits,* when present, plays a decisive part in the preparation for operation of any magnitude and will, in itself,

greatly reduce surgical risk. The patient in poor general condition due to a readily remediable surgical lesion—such as a stenosing duodenal ulcer or carcinoma of the stomach or colon—can now be made relatively safe for even extensive operation by adequate correction of deficits. The details of therapy, however, must be based upon a fairly accurate estimate of the patient's previous losses and his present nutritional status. This can usually be determined on the basis of a good nutritional history, physical examination, and simple laboratory measurements. These deficits should be visualized in terms of the loss of specific body constituents which, biochemically, means protein, water, electrolyte, and vitamins, as discussed previously (p. 161). Of primary importance is the correction of water and electrolyte deficits in the dehydrated patient as discussed in detail in Chapter 9. Transfusions may also be indicated, but only after careful evaluation of the findings, including even accurate blood volume measurements. Complete restoration of all nutritional deficits is seldom possible within the time available, but as many as possible should be corrected.

The time factor is often overlooked in the plan for the correction of deficits. This depends upon the urgency of operation. While it is, of course, obvious that the risk can be greatly reduced by correcting existing deficits, operation sometimes must be carried out in the face of such deficits. For example, the patient may have profuse bleeding within the abdominal cavity that cannot be stopped or does not stop and which has led to continuing shock not responsive to adequate transfusions. In such a case, operation, even though the patient is desperately ill and in shock, offers the only hope of removing the cause of the hemorrhage and thus of giving the patient at least some chance of recovering from an otherwise fatal condition. Another example is the patient with a strangulated intestinal obstruction who cannot be brought into condition for operation by any method and, therefore, requires an exploration for the removal of the lesion which is, in itself, the cause of severe prostration and even shock.

Less urgent operations as, for example, for perforation of an acute appendix, justify a delay of at least several hours for the correction of dehydration and for adequate chemotherapeutic coverage. In other cases, the deficit is less acute or the operation less urgent, permitting many days of preparation which are not only indicated but even necessary to insure a favorable outcome.

3. *Routine preoperative orders* depend on the type of operation and anesthetic, but, in general, they include the following: Soporific drugs such as barbiturates, by mouth, are often used to ensure a good rest the night before operation. An enema is usually given before operation, since the bowels are generally inactive for several days afterwards. Preoperative *catharsis is to be condemned* as a routine because it is apt to increase postoperative nausea, gas pains, vomiting, and distention. However, in colon surgery, mild catharsis to empty the large bowel is used by some surgeons, although the authors oppose it. The field of operation must be adequately prepared by careful shaving and cleansing of the skin over a wide area surrounding the proposed incision. Detergents are useful aids in surface sterilization in operations on the hands or feet. The skin may be prepared for operation with different methods and solutions. A common method utilizes soap, water, and alcohol, but this should not be used in patients with palpable malignant tumors, because of the danger of spreading the tumor by the scrubbing process. Many surgeons use antiseptic agents alone; many are available. Preanesthetic medication is discussed in the chapter on anesthesia.

4. The *transition* from preoperative preparation to postoperative care involves two periods in the experience of the surgical patient: (1) the *operation*, including the anesthetic; (2) the *recovery room*, adjacent to the operating room, for the initial stage of recovery following operation. The importance of a recovery room is now a matter of general agreement, and the benefits have been established without question. The recovery room affords special care for the patient during the early postoperative period which is, of course, of special significance in those receiving a general anesthetic. This period includes the time required for full recovery of vital signs and normal consciousness. Ordinarily this period lasts only a few hours, al-

though in many hospitals the recovery room is designed to care for the patient for a day or two, and thus assumes some of the responsibility ordinarily called *postoperative care.* A thorough discussion of the recovery room will be found in the monograph by Sadove (7).

POSTOPERATIVE CARE

General Considerations. The systemic reaction to operation and anesthesia profoundly affects the character and therapeutic requirements of convalescence (8, 9, 10). All organs and probably all cells are involved in this response, and the load imposed upon systems whose function is already borderline may precipitate overt failure by pulmonary insufficiency, adrenocortical insufficiency, cardiac decompensation, renal failure, hepatic coma, and numerous other complications. Moreover, even if the functional reserve of all organs is normal, the altered activity occasioned by the stress will influence the postoperative treatment. For example, it is usually poor judgment to force oral intake immediately following surgery, when motor and secretory functions of the bowel are altered; the food frequently will be regurgitated by the temporarily indisposed digestive tract. Similarly, extensive hormonal alterations occur after operation which, collectively, impair the capacity of the kidneys to excrete water. Thus, whereas the intravenous infusion of large volumes of fluids not containing electrolytes usually is not hazardous in the normal subject, such an infusion in the postoperative patient may produce water intoxication. Other examples could be cited. The point is that the early stage of convalescence represents a special circumstance which calls for special precautions.

The traditional attitude toward postoperative and post-traumatic care has been one of careful observation for the detection and avoidance of accidents and of symptomatic treatment of clinical manifestations as they arise. Aside from this, no active program has been considered necessary, great reliance being placed upon the natural reparative processes of the body, as discussed above. Nevertheless, instead of depending upon the spontaneous efforts of nature, positive methods of therapy are now employed because they shorten the period of convalescence and reduce many of the complications formerly thought inevitable.

That reparative processes may begin almost immediately following injury is now an acknowledged fact, which means that their beneficial effects may be synchronous with, rather than subsequent to, the effects of injury.

Basic Routine Orders for the Immediate Postoperative Period. Certain general orders are essential following all types of major surgery, regardless of what other orders may be required for special circumstances. These basic orders are:

1. Keep running record of the vital signs. The blood pressure, respiration, and pulse rate should be checked at stated intervals. Measurements should be frequent (every 15 to 30 minutes) until the circulation has stabilized and until the patient is awake.
2. Give nothing by mouth.
3. Record administration intravenous fluids (8).
   a. Finish blood transfusion?
   b. How much, of what type fluid, how fast?
4. Give sedative or analgesic.
5. Note and record early ambulation, diet after patient has passed stage of nausea, antibiotics if to be used, deep-breathing and other exercises in bed, and procedure in case patient does not void within 12 or 14 hours after operation.

The request for frequent rechecks of vital signs ensures that the patient will be seen often—the most reliable means of detecting, at an early stage, still such other complications as external hemorrhage, respiratory obstruction, or prolonged unconsciousness. After the patient is fully alert and his cardiopulmonary apparatus has stabilized, the postoperative hazards rapidly diminish in number and magnitude.

Postoperative Activity and Ambulation. Although immobilization and rest in bed are definitely necessary after operation, it is becoming increasingly apparent that complete immobility in any position is harmful. For example, bed rest and immobilization are known to increase the likelihood of pulmonary and circulatory accidents, to produce atrophy of disuse, and to lead to disturbances in neuromuscular abilities (often called "de-

conditioning") and to certain poorly understood metabolic changes that include calcium mobilization with the risk of kidney stones. Aside from these harmful effects, there are such subjective difficulties as the need for defecation and urination in the horizontal position. Vital capacity of the lungs is known to be impaired also during immobility and rest in bed. Of perhaps still more importance, is the fact that while a patient is at bed rest he is in negative nitrogen balance.

Some confusion has arisen regarding the emphasis on physical factors, especially early ambulation, after operation. These factors should be clarified. In the first place, early ambulation is often taken to mean merely the termination of bed rest, which does give the patient, in many instances, a psychological lift because it means to him the first step in recovery. However, termination of bed rest in itself means very little unless it includes movement of the lower extremities by walking. The patient who merely gets out of bed and sits in a chair may be worse off in terms of promoting blood flow through the lower extremities than if he were lying in bed with the legs elevated. Finally, the beneficial effects of movement in combating the atrophy of disuse and in promoting the circulation of the lower extremities may actually be achieved while the patient is still confined to bed. This is done by instituting a definite program of muscular exercises from the very beginning (see below).

First, the cooperation of the patient is obviously essential and can nearly always be obtained if he understands the details and objectives of the program. This requires a preliminary discussion of such plans, preferably with the family as well as with the patient. Second, the influence of example in any program is always beneficial. Many patients will cooperate much more readily when they are able to see other patients doing the same thing, particularly when the benefits of such action and the absence of danger are apparent. Third, the specific orders must be individualized, based upon the type of operation and the patient. Fourth, the program should start as early as possible, indeed, as soon as the patient awakens from the anesthetic, or in other instances, as soon as he is returned to his bed.

Two general *types of early movement* are nearly always indicated and have few, if any, contraindications. *First, breathing exercises* are started in order to maintain a good interchange of air with all parts of the lungs. This objective may be achieved by ordinary, voluntary deep inspirations for several minutes every hour, preferably in the sitting position, which always increases the vital capacity of the lungs. In patients with actual or suspected patchy atelectasis, deep inspiration and forced expiration are increased by urging the patient to cough while sitting on the edge of the bed with the abdominal and lower costal margin held firmly with a tight binder or by the hands of the doctor or nurse. Such exercises and procedures often aid in clearing the finer bronchioles and, if carried out early, will prevent many postoperative pneumonic complications. The importance of adequate pulmonary ventilation has been emphasized by Dripps and Deming (11), and by Brattstrom (12). *Second, a program of calisthenics* for the upper and lower extremities should be started immediately after operation for 5 or 10 minutes every hour while the patient is awake. This is continued in most cases where bed rest is necessary. Early termination of bed rest, within 24 hours, is usually indicated in nearly all surgical patients after operation unless definitely contraindicated, as discussed below, or opposed by the patient. The first step in early ambulation should be supervised by the surgeon in charge and is preceded by short periods during which the patient sits up in bed with his feet resting on a chair. Once the patient is able to walk, and this is often possible within 24 hours, even after extensive abdominal operations, increasing activity is continued.

The *contraindications* to ambulation are numerous. Severe infection, regardless of its location, is a strong contraindication; so also is high fever, regardless of its cause. Patients who are extremely weak should not be ambulated until improvement in nutrition is attained and exercises in bed have shown some beneficial effect. Cardiac decompensation, recent coronary thrombosis, and pulmonary complications of any significance are obvious contraindications. If, for some reason, an abdominal incision has been closed insecurely, it is usually unwise to get the patient

out of bed for several days, because of the danger of wound disruption.

NUTRITIONAL FACTORS. Starvation following operation and injury has, in the past, been accepted as inevitable or even necessary as part of the effects of injury. The present trend, however, is to combat starvation, beginning immediately after the injury or operation, by proper attention to the nutritional requirements of the surgical patient (see p. 165). Postoperative nutritional care is based upon (*a*) the correction of deficits as they occur, and (*b*) the prevention of deficits which might occur. The former category includes the restoration of losses sustained during operation or after operation, by the adequate administration of whole blood, plasma, water, and electrolyte, as discussed in the previous chapter. The latter category includes the prevention of starvation after operation by the maintenance of a food intake of all the necessary elements in the diet. This is now possible whether the patient is able to eat or not. If he is unable to eat, reliance upon injections of glucose solutions alone, as in the past, will inevitably lead to protein starvation. The inclusion of protein nourishment as amino acid mixtures will prevent, to a great extent, the protein starvation which was inevitable in the past. The addition of vitamins, especially vitamin C, to such a parenteral diet is often of equal importance.

Parenteral alimentation, when indicated, is always temporary, to be terminated as soon as oral intake can be resumed. Indeed, oral intake can usually be resumed earlier if the parenteral diet contains protein, for reasons discussed elsewhere. An adequate dietary intake must therefore be maintained by constant attention to details. Moreover, in those patients who do not require parenteral injections, the same general principle of avoiding protein and vitamin starvation applies from the very beginning. If the patient is unable to take a full, well-balanced diet, it is necessary to give priority to protein and vitamins, inasmuch as wastage of these elements in the body is likely to lead to physiologic impairment. Calories are also essential but may, to a considerable extent, be obtained from adipose tissue which is actually designed to serve this purpose. As a general rule, therefore, the adult patient of average weight should receive, in addition to vitamins, at least 100 gm. of carbohydrate and about 100 gm. of protein as the *minimum* daily requirement until he is able to take a full complement of food.

Postoperative Complications (13). The number and types of complications which may develop after operation are so great that space will permit discussion of only a few of the more important ones.

Beginning immediately after operation, and continuous with the anesthesia chart, are recorded frequent and careful observations of the pulse, respiration, and, in certain instances, repeated blood counts and blood pressure determinations, as noted above. The basic aim is to note early evidence of complications and to ensure their prompt detection and treatment. This objective depends, to a great extent, upon an ever-watchful and alert resident and nursing staff. For example, the first evidence of shock may be an increase in pulse rate. Pneumonia may be suggested quite early by an increased respiratory rate, tracheal obstruction, or restlessness.

Avoiding complications is, of course, a primary objective and, indeed, is frequently achieved, as shown by a prompt return of normal function without significant symptoms even after extensive operations. In the following discussion, only a few complications will be mentioned for they are described in more detail elsewhere in the text. Most of the untoward symptoms are considered, even though many of them are almost "normal," since they occur frequently and soon disappear. Nevertheless, a good postoperative program should aim to prevent them, and, if they occur, to treat them effectively, especially to see that they are not the harbingers of complications. It should be emphasized, however, that many postoperative manifestations are due to the nonspecific systemic and outlying effects of injury, as discussed in detail in Chapter 12.

1. *Pain* is probably one of earliest and and most frequent postoperative complaints, although it may be completely absent. Investigation as to the nature and cause of pain should precede medication. As pointed out by the studies of Beecher (14), anxiety plays an important part in the subjective complaint of wound pain in military and civilian sur-

gery. Simple sedation and attention to psychogenic factors discussed above are often sufficient to produce relief. Morphine is the most efficient drug for the relief of pain, yet, because of its depressive effect on respiration and its tendency to prolong anorexia, it should not be used if other means are effective. Moreover it *should not be ordered as a routine*. The maximum effect on relief of pain itself is usually reached with a moderate dose, e.g., 15 mg. or 0.25 grains; increasing the dose increases its depressant effect without significantly increasing the degree of analgesia. Delay in giving analgesic drugs decreases their effectiveness. A small dose early will do more than a large dose later. Individual variations are frequent. Intravenous injection is the most rapidly effective.

Abdominal pain is obviously most likely after abdominal operations. Most commonly located in the incision, it is due largely to the pressure of skin sutures, particularly when they have been tied tightly. Subcuticular sutures are less likely to be followed by pain. However, this type of pain generally disappears within 24 hours. In many cases, abdominal pain will be relieved by such simple measures as change of position or loosening of tight dressings. When the pain is cramplike and more deeply seated, it is often due to increased peristalsis called "gas pains," particularly when associated with some abdominal distension. Such pain is usually due to air aspirated or sucked into the stomach during or after anesthesia and then passed into the intestines. The origin of gastrointestinal gas in this way has been well studied by several observers, especially by Maddock and associates (15). It can be prevented by manual evacuation of the stomach by the surgeon before closure of the abdomen and by efficient gastric aspiration (Wangensteen) during and after anesthesia, until the patient regains consciousness. When gas pains occur later they will usually yield to such procedures as gastric lavage, the use of a rectal tube, or a small enema. Intestinal obstruction should be suspected if pain is persistent.

2. *Nausea and vomiting*, although frequently absent, may be the most distressing of postoperative symptoms and are not limited to abdominal operations. The anesthetic agent may be the cause; in abdominal operations, the peritoneal trauma, or aspirated air (see above), especially when associated with distension, may be the causative factor. In sensitive patients, the problem may be an especially difficult one. Reassurance and nursing care are particularly effective. Gastric lavage may be necessary, particularly when there is evidence of much gastric retention. A period of 24 hours or more during which nothing by mouth is given and parenteral feeding maintained is advisable before starting oral administration of fluids. However, such simple fluids as water, tea, or unsweetened carbonated beverages can be allowed, if requested. Reassurance, sympathy, and psychotherapy, which should be included under the heading of bedside care, are of extreme importance. They sometimes spell the difference between a rapid and a prolonged convalescence. Patients allowed out of bed early are less apt to suffer nausea and vomiting than those kept in the horizontal position.

When vomiting results in the loss of considerable fluid, dehydration of the blood and tissues inevitably occurs and this, in itself, may provoke further nausea and vomiting. Such dehydration will require correction, with sufficient parenteral fluid to replace the loss, the details of which have already been discussed. An accurate record of intake and output is useful in estimating the degree and correction of dehydration.

If nausea and vomiting continue for several days after adequate therapy, the existence of such a serious complication as intestinal obstruction, general peritonitis, enteritis, wound disruption, and, particularly, *acute dilatation of the stomach* should be suspected. The latter is accompanied not so much by pain as by distention and repeated regurgitation of small amounts of fluid. It is really a neurogenic disorder and is often secondary to retroperitoneal hemorrhage or spinal or pelvic fractures. Treatment is specific and consists of evacuation of the stomach through a nasal catheter or a stomach tube as frequently as necessary. An indwelling tube—as initially recommended and popularized by Wangensteen, provided with continuous mild suction, and inserted at the time of operation—will effectively prevent dilatation of the stomach and is widely used as a routine procedure after intraabdominal operations. Such gastric

decompression may be continued for several days to prevent gastric retention and dilatation, and then used as a guide in determining when the oral administration of fluids and food is safe. This is done by clamping the tube at intervals and observing the behavior of ingested fluids. If no retention occurs and gastric emptying is prompt, the tube is removed and an increasing diet started.

3. *Insomnia* is frequently serious enough to require specific attention. Good nursing, absence of noise and excitement, and elimination of disturbing psychogenic factors, as already discussed, are obviously important. Relief of pain is axiomatic. Pharmacologic means must sometimes be used; the barbiturates by mouth or chloral hydrate or paraldehyde by rectum are usually quite effective, provided an adequate dose is employed. Up to 1 gm. (15 grains) of chloral hydrate is safe and may be necessary to achieve sufficient sedation. Codeine in conjunction with a barbiturate is often more effective than either alone even when used in small doses, e.g., 30 mg. and 60 mg. respectively. Morphine may be used as a last resort but is very seldom justified or necessary in the absence of severe pain.

4. *Failure to urinate* may be due to urinary retention, as already discussed. However, oliguria or anuria must always be suspected, particularly when there is no pain or distention and when bladder dullness is absent. A diagnosis requires catheterization. The cause of anuria may be actual disease of the kidney, functional or organic obstruction to the ureters, or transient suppression of secretion from dehydration. Differential diagnosis is important for renal impairment (lower nephron nephrosis) is aggravated by giving large volumes of fluid whereas dehydration requires such therapy. Renal insufficiency calls for limiting the fluid intake to insensible losses which normally are not over 1,000 ml. per day, i.e., 1 liter of 10 per cent glucose in water. In any case, renal complications present a difficult therapeutic problem, including the removal of such causes as damaged tissue in extensive wounds (16).

5. *Pulmonary complications*, though now fairly rare thanks to better anesthesia and to prophylactic chemotherapy, are still a hazard (17). Aspiration pneumonia is still too frequent (18) and is due to actual aspiration of regurgitated gastric contents into the lungs immediately after operation. The terminal changes are described in the excellent postmortem studies of Irons and Apfelbach (19). Aspiration pneumonia should be minimized or completely prevented by adequate gastric lavage before, during, and after operation whenever considerable gastric retention is present. Expert anesthesia and the increasing use of the recovery room have reduced this hazard considerably. Pulmonary edema caused by excessive transfusion of blood or by too much fluid (especially if more saline than indicated) is also becoming more uncommon. Since it is iatrogenic, such a complication is really inexcusable.

Postoperative pulmonary complications depend, in general, upon the length and type of operation, increasing age, recent upper respiratory infections, expertness of anesthesia, and gentleness of the surgeon. Upper abdominal procedures are especially likely to provoke pulmonary complications. Recognition is based upon the development of rapid respiration, fever, thoracic pain, dyspnea, cyanosis, and cough. When atelectasis is massive, i.e., involving an entire lobe, such characteristic physical signs as hyperpnea, absence of breath sounds over the affected area, and a shift of the mediastinum to the involved side are present and diagnostic. Pulmonary embolism is usually manifested by sudden thoracic pain, respiratory and circulatory impairment, and expectoration of blood-tinged sputum, occasionally by shock alone. Roentgenography may be very helpful for differentiating the various lesions, but a portable apparatus should be employed for the very ill patient.

The early use of pulmonary exercises, as already mentioned, and prophylactic chemotherapy, where indicated, will also tend to prevent many cases of patchy atelectasis and probably other types of pulmonary involvement. Once a definite pulmonary complication is present, treatment is largely medical and in nearly all cases calls for the intensive use of chemotherapy, based if possible on identifying the organisms and determining their sensitivity to various agents. In massive atelectasis, evacuation of a bronchial plug is specific and often dramatically effective; it

can sometimes be induced by rolling the patient from side to side and supporting the abdominal wall while the patient coughs. Aspiration of the bronchi by means of a catheter passed through the glottis is also effective. Bronchoscopic removal of the obstructing plug may be indicated if simpler measures fail to promote aeration. Oxygen therapy is useful, particularly when it is started early. In pulmonary embolism, papaverine (grains ½) and atropine (grains $\frac{1}{150}$), have been found to be of value by de Takats and Jesser (20). Anticoagulant therapy, starting with intravenous heparin, is usually indicated.

Aerosol therapy is a useful adjunct in many pulmonary conditions and may be helpful in postoperative atelectasis. In atelectasis, the dried, thickened mucus blocking the bronchioles and the smaller bronchi is often extremely tenacious and difficult to expel. Such detergent wetting agents as superinone (alevaire) or tergemist tend to overcome this difficulty by liquefying these thickened secretions. Special nebulizers are provided with oxygen or air so that the agent is *inhaled by the patient* in the form of an aerosol (fog). Aerosol therapy has also proved helpful early after tracheotomy. These wetting agents, in addition to liquefying secretions, serve to humidify the dry anhydrous oxygen being given patients. Aerosol therapy is also useful in the intrabronchial administration of such antibiotics as penicillin, of such bronchodilators as isoprel or epinephrine, and of certain enzymes as tryptar, which also aids in liquefying tenacious secretions. However, these agents are often of little or no value.

6. *Surgical shock* is discussed in a separate chapter. When it occurs following operation, more or less the same clinical manifestations develop as after any other trauma, except for the masking influence of the anesthetic. General anesthesics affect the sensorium, and thus make it difficult to judge the degree of cerebral anoxia. Knowledge of the operative procedure, however, helps in estimating the likelihood of internal hemorrhage, which, if severe, may necessitate a second operation to control the bleeding. Treatment is described in the chapter devoted to shock.

7. Surgical shock may be mistaken for *cardiac failure,* a fortunately rare postoperative event, which is manifested by dyspnea, cyanosis, and, later, by evidence of pulmonary edema. The circulatory impairment is evident by the appearance of a fast and often irregular pulse. In cardiac failure, the intravenous injection of a large volume of fluids is obviously contraindicated and may provoke an immediate fatality. Indeed, venesection or venous tourniquets may sometimes be indicated rather than intravenous injections. Oxygen therapy by inhalation, preferably under positive pressure, is perhaps the most important feature in treatment. Appropriate supportive cardiac therapy should be given as indicated in the individual circumstances. The use of hexamethonium may diminish the central blood volume.

8. *Fat embolism* is a rare postoperative and post-traumatic complication and is associated with a high mortality. It was originally thought to be due to the entrance of fat into the blood from the traumatized bone marrow. Lehman and Moore (21), however, presented evidence that the fat in the blood is indigenous, being formed by a change in the physical character of the blood lipoids. Symptoms are of two types, one circulatory, the other pulmonary. Ophthalmoscopic examination may show retinal vessels filled with fat. A diagnosis can sometimes be made by finding fat in the sputum or urine (Warren, 22). Treatment is that of shock and pulmonary complications in general. *Air embolism* is usually serious only after operations involving the pleural cavity, because of the access of air into the pulmonary vein which carries it to the left heart and thence to the brain, thereby producing signs of cerebral embolism.

9. Unfortunately *thromboembolic disease* is still a fairly common and serious postoperative complication. Pulmonary embolism rarely follows thrombophlebitis femoris (phlegmasia alba dolens, milk leg), but occurs with a type of thrombosis first described by Payr in 1930 and by Homans (23) in 1934 as a "thrombosis of the deep veins of the lower leg," in which a long clot attached only at one distal point, usually the plantar veins of the foot, extends proximally, floating freely in the blood stream and easily detached to form a large embolus. The term phlebothrombosis was later applied to this

lesion by Ochsner and DeBakey (24). Such a clot forms because of (*a*) slowing of venous blood flow; (*b*) changes in the blood, producing more rapid coagulation; and (*c*) endothelial injury. Based on these causes, prevention as the most effective form of therapy could be achieved readily by (*a*) increasing venous return from the legs by early postoperative movement and muscular exercise of the feet, (*b*) the use of anticoagulants, and (*c*) prevention of injury to the veins of the leg, respectively. Of these methods, the first is clearly the most physiologic. Once a deep thrombosis has started, movement is probably harmful by aiding in its dislodgement, whereas anticoagulant therapy should halt its propagation and reduce the likelihood of embolism. Early exploration of the vein proximal to the thrombosis, removal of the clot, and ligation of the vein was recommended (Homans) years ago, but is seldom carried out now. The clinical detection of phlebothrombosis may be difficult, but the earliest sign is deep tenderness in, and on dorsiflexion of, the foot. Injury to the plantar fascia, however, may produce the same signs. Fatal pulmonary embolism is by no means limited to surgery; it is still seen in medical and obstetrical cases (25). It is much less common in young patients than in elderly patients; accordingly, more active prophylactic therapy is indicated in the latter group. A thorough and critical review of postoperative thromboembolic disease has been reported by DeBakey (27).

10. *Infection* of an operative wound may be serious, especially in large incisions. Such infections are often ushered in by an unexplained increase in the temperature, an increased local tenderness, and redness or swelling of the wound, but in some cases may be present silently. Further details will be found in Chapter 14.

11. *Postoperative fever* may be self-limited and due merely to the effects of absorption of damaged tissue, especially of hemoglobin. When fever is high or persistent, another cause must be sought. The most common are pulmonary, urinary, or wound infections. Occasionally it is due to chemotherapy.

12. *Wound disruption* (*dehiscence*) is still too frequent, especially after anterior abdominal incisions, and traditionally is supposed to be due to persistent coughing or retching, which undoubtedly plays an important role in some cases. Nutritional deficits, especially in protein and in vitamin C, are also responsible in some measure. More often, however, the fault lies in such imperfect technic during closure as sutures tied too tightly, the use of continuous rather than interrupted sutures, and the inclusion of insufficient fascia in the suture.

The first indication of complete wound disruption may be the sudden appearance of excessive serous discharge on the dressing. To an inexperienced surgical intern the sight of coils of intestine after removal of the dressing is a memorable experience. However, it is not as serious as might be expected. A high mortality rate is associated with this complication, primarily because it often occurs in patients who are seriously ill; it is particularly common in elderly patients with cancer or jaundice. Peritonitis or herniation can usually be avoided if the wound is promptly closed. This must be done under local or general anesthesia. Many closely placed, through-and-through sutures are used, each of which includes all layers of the abdominal wall.

More commonly, disruption of the wound is incomplete and is limited to the deeper layers of the incision which may produce some of the manifestations of intestinal obstruction (particularly nausea, vomiting, and distention) and lead eventually to the formation of a ventral hernia.

13. *Fecal impaction* is a fairly common postoperative complication in elderly patients. It is readily diagnosed by rectal examination, but will be overlooked unless such an examination is made. A fecal impaction will not necessarily result in absence of bowel movements; many of these patients indeed have frequent, but small, liquid stools. Considerable rectal pain and tenesmus may be present, particularly at each attempt to move the bowels. A severe grade of fecal impaction may be associated with so much abdominal pain and distension that a diagnosis of intestinal obstruction may be made. These manifestations are so readily relieved by removal of the impaction that a rectal examination should not be delayed whenever the condition is suspected. An oil enema, followed

in several hours by a soapsuds enema, is occasionally effective in softening and expelling the fecal mass, but when the impaction is hard, as is usually the case, the mass *should be broken up by digital manipulation.*

The use of enemas to promote early bowel movements was popular years ago, but no longer is. With diminished food intake there is no need for an early bowel movement; besides, with early ambulation a spontaneous evacuation usually occurs after three or four days.

14. *Neurologic complications* are rare except in operations on the central nervous system. Pressure on peripheral nerves in the operating room has already been discussed. The signs of water intoxication, as discussed elsewhere, are often mistaken for those of cerebrovascular disease, as dramatically described in a recent experience (27). "Toxic psychosis" is a term given to neurologic manifestations due especially to uremia and to severe infections, each of which may occur during the postoperative period. Other psychic disturbances during the recovery phase may be due to transient cerebral anoxia or to unexplained causes. Fortunately they disappear as the patient regains consciousness.

ANESTHESIA

The great progress made in anesthesiology during the past two or three decades has been due to the fact that the modern anesthesiologist is also trained in various basic sciences including pharmacology, physiology, and biochemistry. This additional knowledge has made it possible to understand better the effects of the various anesthetic agents and to extend the frontiers of anesthesiology. This expansion of anesthesiology has stimulated the surgeon to enlarge the scope of surgery and has made possible the rapid progress made in thoracic and cardiac operations (1, 2, 3, 4).

No anesthetic is ideal; the advantages and disadvantages of the various agents can best be appreciated by close cooperation between the surgeon and the anesthetist. An attempt should be made to choose the anesthetic or combination of anesthetic agents best suited for the patient. Since anesthesiology has become a specialty of its own, only the general principles will be discussed here.

Analgesia implies loss of sensation to pain without loss of consciousness. *Anesthesia* implies loss of all sensations.

GENERAL ANESTHESIA

General anesthesia may be administered by several different routes: 1. inhalation; 2. intravenous; and 3. rectal. The anesthetic agents are carried to the central nervous system before anesthesia is produced.

In addition to causing loss of sensation, anesthetic agents possess the power of eliminating motor nerve impulses, which results in more or less complete muscular relaxation. This property is possessed by the agents in varying degrees and determines, in part, the choice of anesthetic, depending on the degree of muscular relaxation required for a particular operation. Different parts of the central nervous system are affected by different concentrations of the various anesthetic agents; the medulla is relatively resistant. This makes it possible to produce safe levels of anesthesia without undue depression of vital centers.

Preanesthetic Medication. Legitimately regarded as part of the anesthetic procedure is the administration of preanesthetic drugs, which are of two major types. One group, including morphine, meperidine (demerol), and pentobarbital (nembutal), acts as a sedative, minimizing apprehension, and thus reduces the amount of anesthetic agent required for induction; this results in a smoother anesthesia. The other type comprises the belladonna drugs, primarily atropine and scopolamine. Atropine will minimize pharyngeal secretions, reducing the tendency to obstruction and aspiration into the lungs. Similarly, scopolamine will dry secretions and has the advantage over atropine in that it also produces some psychic sedation and amnesia. The dosage of these drugs should be carefully individualized. The aged require much less sedation than young adults; factors which alter the metabolic rate will correspondingly increase or decrease the dosage required. Sthenia, fever, pain, excitement, and hyperthyroidism will increase the amount of premedication required. The anesthetic agent to be used and the degree of relaxation to be achieved also modify the dosage. Nitrous

oxide and ethylene call for heavy sedation, ether for moderate sedation, and cyclopropane for very light sedation to avoid respiratory depression. Paradoxically, the deeper the anesthesia required, the lighter should be the preliminary sedation because heavy sedation causes respiratory depression, which may lead to hypoxia, and slows or prevents the administration of enough inhalation agent to produce deep anesthesia.

Stages of General Anesthesia. General anesthesia is divided into four stages. The first is the stage of *analgesia* in which there is a progressive loss of sensation but not of consciousness. The second is the stage of *excitement* during which the patient, though already unconscious, tends to exhibit a hyperactivity which occasionally requires forcible restraint. The third is the stage of *surgical anesthesia* during which operations may be carried out. There may be certain reflex responses to stimuli, but these diminish and relaxation increases as anesthesia deepens. The fourth stage is that of complete *respiratory paralysis.*

Signs of Anesthesia. *Sensory* perception disappears early although stimuli which ordinarily give rise to pain may give rise to a reflex action in the early stages of anesthesia. During the *first stage* of anesthesia, motor power is retained although it may be purposeless. During the *second stage,* voluntary control of movement is lost, but reflex responses are maintained; in fact, they may be violent. During the *third stage,* response to sensory stimulation is lost and the tone becomes weaker. This stage is divided into four planes. Entry into the first plane is indicated by loss of the eyelid reflex; into the second plane by cessation of eyeball movement; into the third plane by beginning intercostal paralysis; and into the fourth plane by complete intercostal paralysis, breathing being entirely diaphragmatic. In the *fourth stage* there is complete motor relaxation and respiratory paralysis; it is therefore dangerous.

Respirations undergo several changes as the anesthesia deepens. During the first stage, breathing is under voluntary control although the patient may hold his breath or breathe rapidly. During the second stage, breathing becomes irregular. As the patient enters the third stage, it becomes regular and automatic; inspiration and expiration are equal in duration and amplitude. As anesthesia deepens, inspiration becomes shorter and gasping while expiration lengthens, is less forceful, and is followed by a gradually lengthening pause, until all respiratory effort ceases.

Eye signs are slightly helpful in determining the depth of anesthesia. During the first stage, the eyelids and eyeballs move in a reflex and voluntary manner. During the second stage, the lids are rigid and light-reflex active. As the patient enters the third stage, the eyelid reflex is lost and voluntary movements cease. In the second, third, and fourth planes of the third stage the eyeballs are fixed, looking straight forward. In the fourth plane, the pupils dilate and light reflex is lost.

Circulatory signs are very important in determining the stage of anesthesia, and, of more importance, they give an indication as to the physiologic status of the patient. If bleeding is uncontrolled or if blood loss is not replaced by adequate transfusion, the *blood pressure* falls. It also falls if the anesthesia becomes too deep. It may rise or fall as a reaction to numerous other factors such as hypoxia, hypercarbia, and reflex stimuli. On many occasions, the exact cause is not apparent, but the deviation from normal is an indication that a pathologic condition has developed; the anesthesiologist must find the cause and correct it as soon as possible. The *pulse* varies greatly depending upon numerous factors including those mentioned above. A change in quality or rhythm may be indicative of myocardial failure. The anesthesiologist must know the pulse rate at all times to obtain the very earliest indication of cardiac distress, particularly since *cardiac arrest* is such a serious complication requiring immediate corrective treatment (within four minutes of onset). The color of the skin is very important. Cyanosis is an index of reduced hemoglobin in the blood, related to oxygen deficiency, but lack of oxygen may be present long before the development of cyanosis. *Pallor* indicates vasoconstriction and may be an early sign of shock even before hypotension. *Capillary tone* is depressed by deep anesthesia and shock and can be measured in the nail bed by the capillary refilling time, i.e., the time required for the return of color after blanching by pressure.

Recovery from Anesthesia. The immediate postoperative period is of special importance inasmuch as several hours may elapse before consciousness is regained, particularly if ether has been given. Aspiration of vomitus is one of the greatest dangers in the recovery period and may occur despite an indwelling gastric catheter. For this reason, it is essential to have the patient on his side during the recovery phase. Vomiting is perhaps more common following ether, but any anesthetic may produce nausea and vomiting. It is true, however, that aspiration of vomitus is less likely following a gas anesthetic because the patient may have recovered sufficiently within 5 or 10 minutes following cessation of administration of the anesthetic to prevent it. Another important danger in the recovery period is obstruction of the airway, which is usually caused by the tongue falling back against the pharynx or by laryngeal spasm. Audible stridor will be noted; if the obstruction is severe or persistent, cyanosis and the serious effects of anoxia will develop. It may be necessary for a nurse or physician to hold the angle of the jaw forward to maintain an open airway; however, a metal or rubber "airway" usually will hold the tongue forward and relieve the obstruction. While the patient is unconscious, the lateral position is preferable. The patient recovering from an anesthetic should be covered with no more blankets than a conscious patient even though he is in shock. Experience during the past several years indicates that assignment of newly operated patients to a recovery ward for 2 to 24 hours will save many lives because of better facilities and care by nurses who are specially trained in complications occurring in the immediate postoperative period.

Hypotension during recovery from an anesthetic is not unusual and may be due to innumerable causes. Important among these causes are hemorrhage, change in position (e.g., lithotomy to horizontal), change from high to low oxygen or carbon dioxide content of the inspired gases or air, cardiac disease, pain, excessive narcosis, and transfusion reaction. Details may be found in a publication by Barbour and Little (5). This complication is a serious one demanding accurate and early diagnosis because persistence of a low blood pressure may lead to oliguria and cerebral damage and because treatment is so varied. Perhaps the most important cause demanding most urgent therapy is hemorrhage. If the hemorrhage is internal, its detection may be difficult unless accurate determinations of blood volume are available because changes in hematocrit or hemoglobin levels are delayed for hours. Regardless of the cause, postoperative hemorrhage must be stopped promptly; since it is commonly internal, from one of the body cavities, the patient usually must be taken back to the operating room. Regardless of the cause of the hypotension, administration of a vasopressin may be indicated to prevent serious sequelae such as oliguria and cerebral damage. Of the vasopressins available, levarterenol bitartrate (Levophed) and phenylephrine hydrochloride (neo-synephrine hydrochloride) are most commonly used. If used, they should not be mixed with whole blood or plasma but should be given in physiologic saline or in 5 per cent glucose solution. If levarterenol bitartrate is used, 4 ml. of a 0.2 per cent solution is placed in 1,000 ml. of saline or glucose solution, and this solution is allowed to go in slowly at first (one drop every 5 or 10 seconds). If phenylephrine hydrochloride is used, 1 or 2 ml. of a 1 per cent solution is put into a liter of fluid. A blood pressure cuff must be kept in position and readings taken every few minutes. As the blood pressure recovers, the intravenous administration is discontinued.

The Airway. Of primary importance in giving any anesthetic is the patency of the air passages. After relaxation occurs, the tongue tends to drop back, and, aided by the accumulation of mucus, a partial obstruction of the pharynx may thus occur. This is avoided to a large extent by elevation of the patient's chin and by holding the head back, the fingers of the anesthetist grasping the undersurface of the mandible for this purpose. If difficulty in the free passage of air is still present as shown by the forcible respiratory efforts of the patient, a curved, flattened, metal or rubber tube (called an airway) is inserted between the teeth above and behind the tongue to overcome the obstruction (Fig. 1).

For the relief of upper respiratory obstruction which will not yield to simpler methods or as an assurance that such obstruction will

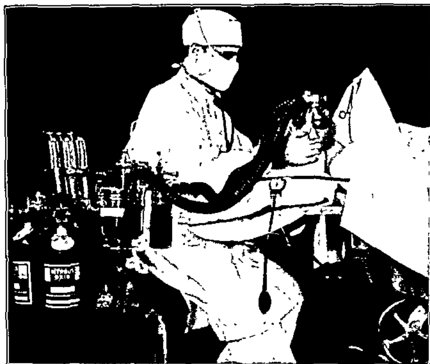

Fig. 1. Method of introducing anesthesia utilizing a "circle filter" type of apparatus. Jaw can be held forward by either the left hand holding the mask or the right hand pushing the ramus forward. A blood pressure cuff and stethoscope on the arm permit constant observation regarding the blood pressure level.

not ensue, an endotracheal tube may be used. A specially constructed catheter, large enough to almost fill the glottis, is passed through the larynx into the upper trachea. This method facilitates the use of positive pressure and is indispensable in operations on the widely opened pleural space and in operations about the head and neck where anesthetic apparatus would otherwise encroach on the surgical field.

Technics of Inhalation Anesthesia. The simplest method for the administration of volatile agents such as ether and chloroform is the *open drop* technic. The drug is dropped on a gauze-covered wire mask where it vaporizes and permeates the air being inhaled by the patient. Another simple but less commonly used method is *insufflation* in which air, laden with ether or some other agent, is blown into the mouth of the patient thus obviating the need for a mask. The most common method of administering anesthetic gases or volatile agents is that utilizing a gas machine by which the concentration of the agent in oxygen can be controlled. The amount and type of rebreathing are important features and are the basis for the following classification.

1. The *closed* method (carbon dioxide not removed) is one in which the anesthetic agent and oxygen are inhaled from a bag and closely fitting mask through which the gases are completely rebreathed. Owing to the rapid accumulation of carbon dioxide, this method is not physiologic and can be used safely only for very short periods.

2. The *semiclosed* method uses a bag and mask, but the flow of gases is maintained at a sufficient rate to eliminate much of the exhaled carbon dioxide and anesthetic agent through an escape valve. Some excess carbon dioxide usually develops. Moreover, the loss of anesthetic gases proves quite expensive.

3. In the *open* technic, the exhaled gases are prevented by a valve from being rebreathed, so that on each inhalation the patient receives a fresh mixture. Accumulation of carbon dioxide is avoided, but the expense is much greater because of loss of the anesthetic agent.

4. In the *carbon dioxide absorption* technic (Fig. 2), the anesthetic agent and oxygen

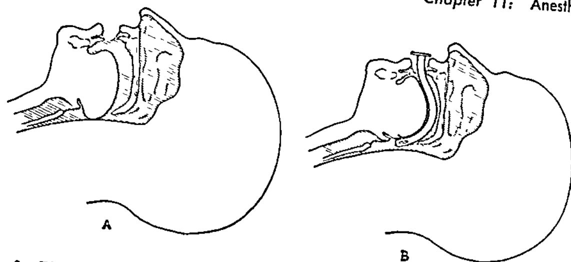

Fig. 2. Diagram illustrating the use of pharyngeal airway. A, obstruction caused by apposition of the tongue to the posterior wall of the pharynx; B, obstruction relieved by insertion of metal airway.

are rebreathed, but the exhaled carbon dioxide is removed by passage of the mixture through an absorbing chemical (e.g., soda lime). Oxygen is added constantly to replace that used by the patient, and the anesthetic agent is added as needed. This method is the most economic in conserving the anesthetic agent and has other distinct advantages. Two types of mechanical arrangement are used. With the "to-and-fro" system there is a canister of absorbent chemical inserted between the mask and bag, and the air is breathed back and forth through it. With the so-called circle filter (Fig. 3), the air passes around a one-way circuit through two breathing tubes leading to and from a canister of absorbent chemical on the machine, beyond which is a breathing bag. The direction of flow is controlled by valves.

Accumulation of carbon dioxide, or respiratory acidosis, is highly undesirable, and all efforts are made to avoid this. Convincing evidence of the harmful effects of excessive carbon dioxide has not yet been obtained in man, but certain facts seem established. Cardiac arrhythmias are more likely to develop during respiratory acidosis. This may be related to the liberation of norepinephrine and epinephrine by carbon dioxide. Sudden changes in carbon dioxide tension are reflected in changes in potassium balance. This may contribute to irregularities of the heart and to hypotension.

Respiratory Emergencies. The frequency of respiratory emergencies during and immediately following operation emphasizes the fact that the person giving the anesthetic should be well-trained and familiar with the various complications of anesthesia, since only prompt action of the correct type, often in cooperation with the surgeon (6) will avoid unnecessary fatalities.

1. Respiratory Paralysis. The cause of this complication may be central, as in the fourth stage of general anesthesia, or may be due to acute oxygen want; it may occur in spinal anesthesia, due to peripheral (phrenic and intercostal nerves) or central paralysis. In the absence of respiratory obstruction, efficient artificial respiration with air or oxygen will maintain life while the cause is detected and eliminated. Severe respiratory depression without actual paralysis, as may occur in very deep third stage anesthesia, although less dramatic, may cause serious results from oxygen want (hypoxia) if allowed to persist; the cerebral hypoxia may produce serious mental deterioration.

2. Acute Respiratory Obstruction. This may result from many causes common among which are the relaxed tongue falling back against the posterior wall of the pharynx; foreign bodies such as chewing gum, false teeth, sponges, vomitus, mucus, pus, and blood in the air passages; laryngospasm; tumors; edema. Acute respiratory obstruction precipitates respiratory efforts which are persistent and exaggerated until abolished by the ensuing acute oxygen want. These futile respiratory efforts have a characteristic appear-

ance—the abdomen expands while the chest is drawn in, particularly at the lower ribs, the sternum, and the suprasternal and supraclavicular regions. Treatment depends on the nature of the obstruction and may consist of elevating the chin, pulling the tongue forward, insertion of an airway or an endotracheal tube, digital or instrumental removal of a foreign body, and suction or gravity drainage of fluid from the pharynx or trachea. Any

obstruction at or above the larynx can be relieved by a quick tracheotomy if other methods fail. If acute oxygen want remains unrelieved and respiratory efforts have ceased, correction of the obstruction must be followed by artificial respiration (see page 179).

3. ACUTE OXYGEN WANT. Usually called *anoxia*, an acute lack of oxygen may result from interference with respiration or from the administration of a mixture containing too little oxygen. The outstanding signs are change in pulse rate to either tachycardia or a slow full bounding pulse; increased respiratory rate followed by respiratory arrest; muscular spasms resulting in movement of the limbs, vomiting, phonation, rigidity, or severe tonic convulsions. Cyanosis sometimes but not always occurs, since the appearance of cyanosis depends upon many factors including the amount of hemoglobin, the texture and color of the skin, and the distribution of the blood. The treatment is obviously to remove the cause and administer oxygen or air. It should be emphasized here that anoxia is to be meticulously avoided, regardless of the type of anesthesia used. Much harm is wrought by anoxia especially in poor risk patients and in those with circulatory shock (see Ch. 13).

In the treatment of acute respiratory emergencies, stimulant drugs or carbon dioxide are of little use particularly in the presence of obstruction. The essential thing is to supply adequate oxygen without delay and to remove the cause.

Cardiac Arrest. Cessation of cardiac activity due to acute cardiac failure, ventricular fibrillation, or autonomic reflex stimulation is fortunately much less common than cessation of respiration, but on the other hand it is much less likely to respond to treatment. Its possible causes should be avoided, particularly anoxia (7), hypercarbia, and unusual reflexes. If the heart stops, respirations will likewise soon cease, thus making artificial respiration necessary. Artificial respiration with oxygen, along with cardiac massage (better called manual artificial circulation), should restore cardiac rhythm and life if the cardiac arrest was detected as soon as it happened and proper measures were instituted immediately (within 4 minutes). By "manual artificial circulation" is meant firm but gentle intermittent compression of the heart about 60 times per minute to empty the heart; it refills of itself. This is best done by an approach through the chest. A lateral incision is made from the border of the sternum in the third or fourth left interspace, the adjacent cartilages are cut, and the ribs are spread apart. Time is important, but an effort must be made to maintain as aseptic a technic as possible. In the presence of efficient artificial respiration and artificial circulation, oxygenation of the tissues (particularly the brain) is maintained. If ventricular fibrillation develops, it will usually be necessary to use a defibrillator to restore rhythm, although the rapid injection of 20 ml. of 1 per cent procaine into one of the large arm veins may be tried first (8). Calcium chloride, 2 to 10 ml. of a 10 per cent solution, injected into the left ventricle may be helpful in initiating cardiac rhythm or in improving the beat if it is weak. In the defibrillated heart, epinephrine is dangerous.

A method of external electric stimulation which acts as an intracardiac pacemaker has been reported by Zoll and associates (9). Unfortunately this procedure is not always successful, and if it is not, it may prevent restoration of the heart beat by the conventional method of cardiac massage. Return of spontaneous cardiac action has occurred as long as 90 minutes after such treatment was instituted, ultimate recovery of the patient being complete. However, a complete cessation of cardiac action for more than six minutes is incompatible with life, even if cardiac action returns; this is due to the fact that there is functional death of the cells of the central nervous system, consequent to interruption of the blood supply.

ARTIFICIAL RESPIRATION

On numerous occasions, the anesthetist will be confronted with cessation of respirations produced by complications of anesthesia including overdose of anesthetic, anoxia, and overdose of preanesthetic drugs. When respiratory arrest occurs in the operating room, artificial respiration will be a comparatively simple matter since the ordinary gas machine is most effective for such a purpose. Obviously, when respiratory arrest is encountered

outside the operating room, other means must be adopted.

Waters (10) has emphasized four facts about artificial respiration: 1. gentle intermittent inflation of the lungs with air can serve as an adequate substitute for normal breathing; 2. if oxygen is available, it may be used; 3. regardless of the method employed, air cannot enter or leave the lungs if the air passages are obstructed; and 4. elaborate equipment is not essential.

A simple *mechanical method*, described in detail by Waters (10), which eliminates the need for elaborate machines, consists of the use of an oxygen tank, a rubber bag, and a face mask. The valve of the oxygen tank is opened, and the mask is applied to the face. Interchange of oxygen is achieved by alternately squeezing the bag and releasing it. With this method, it is essential to be sure (as in other methods) that a free interchange of gas to and from the lungs is obtained. Firm pressure against the angle of the jaw forcing it forward will usually correct obstruction caused by the tongue falling backward, which is probably the most frequent and important cause of obstruction to artificial respiration.

Without question one of the most useful and most neglected methods of artificial respiration is *blowing into the patient's nose or mouth* (Fig. 12, p. 180). This is often called the mouth-to-mouth method (11). It may be necessary to lift the jaw forward to allow free passage of the air into and out of the lungs. In addition to the use of the gas machine mentioned above, several manual methods are available. The *Nielsen Method*, consisting of alternately lifting the arms and pressing on the back with the patient in the prone position, is effective (Fig. 13, p. 181). The *Schaefer Method* consists of pressure over the lower part of the dorsum of the chest by the operator's hands with the patient in the prone position. The *Silvester Method* is performed with the patient in the supine position; it consists of expansion and deflation of the patient's chest by elevating the patient's arms to full extension over his head (equivalent to inspiration) and deflation of the chest by pressure of the arms against the chest. In the *Eve method* the patient is placed on a door or large board balanced in the middle, and the patient's head is alternately elevated and lowered; the weight of the liver causes upward and downward movement of the diaphragm with resultant exchange of air in the lungs.

After a study of eight of the more commonly used methods (excluding use of mechanical devices), Gordon and associates (11a) found that a back-pressure hip-lift method combining the Schaefer (prone pressure) and Emerson (hip lifting) methods resulted in the interchange of almost twice as much air as with any other method.

AGENTS USED IN GENERAL ANESTHESIA

Although ether was one of the first anesthetic agents discovered, it is still used and perhaps more commonly than any other. However, numerous other agents have been introduced in the past two or three decades, many of which have specific advantages for certain types of patients or operations.

Ether. Diethyl oxide ($C_2H_5OC_2H_5$) was first used as a surgical anesthetic in Jefferson, Georgia, by Dr. Crawford W. Long, who in 1842 painlessly removed a tumor from the neck of a patient. Its widespread use followed an independent public demonstration of its value at the Massachusetts General Hospital in Boston in 1846. Ether (also called sulphuric ether) is a volatile liquid which is administered by inhalation of the vapor, which, in a warm atmosphere, is rapidly given off by the liquid.

ADVANTAGES OF ETHER. It is probably the most widely used general anesthetic for the performance of operations requiring good muscular relaxation. It is also used extensively in children. It has a wide margin of safety; i.e., there is a considerable range between the amount of ether which produces anesthesia and the amount which is toxic. Ether is one of the most convenient of inhalation anesthetics since it requires only a simple gauze mask for its administration and is perhaps the safest in inexperienced hands.

DISADVANTAGES OF ETHER. The slight though definitely deleterious action of the drug itself on liver cells makes it somewhat dangerous in patients suffering from a severe degree of hepatic disease. In surgical shock it is especially hazardous since it has an un-

favorable effect on a falling or low blood pressure. It does not act as rapidly as other anesthetics and is not, therefore, advisable for short operations. Ether tends to increase the postoperative nausea and vomiting. Its flammable property makes it dangerous when a hot cautery or flame is being used in the operating room, although some of the gases are probably more hazardous in this regard.

Nitrous Oxide. Though known before as an interesting gas, nitrous oxide was first used as an anesthetic agent in 1844 by Dr. Horace Wells, a dentist of Hartford, Connecticut, for the extraction of teeth. Nitrous oxide (N_2O) was originally called laughing gas because of the hilarious mood it sometimes provoked in patients. It is always given mixed with oxygen in varying percentages and is, of course, administered with a gas machine. Nitrous oxide will support combustion as does oxygen but is not, itself, combustible or explosive. It is not a very potent anesthetic.

ADVANTAGES AND DISADVANTAGES. Nitrous oxide acts fairly rapidly; its effect is over just as quickly, and there is no disagreeable odor as is true of ether. It produces very little muscular relaxation, since at best it can produce only first plane anesthesia (of the third stage) and in some individuals not more than second stage anesthesia without severe oxygen want. Its margin of safety is not very wide even though the gas is in itself not toxic, because its effectiveness depends on a rather high concentration of the gas, often as high as 90 per cent or more, thus leaving less than 10 per cent of oxygen to carry respiratory function. Asphyxia, therefore, is the dangerous feature in nitrous oxide anesthesia and requires expertness to avoid it. It is thus a more difficult anesthetic to give than ether. The rise of blood pressure and slowing of the pulse rate by nitrous oxide are apparently due to the effect of asphyxia.

Nitrous oxide–oxygen inhalation finds an ideal application in short operations when relaxation is not essential. It is used most commonly in the extraction of teeth, incision and drainage of abscesses, skin grafting, and removal of superficial tumors. It may be given after any of the basal anesthetics mentioned and, with their aid, may bring about sufficient relaxation to permit pelvic and abdominal operations.

Nitrous oxide is a weak anesthetic; however, this disadvantage can be overcome by increased dosage of preanesthetic drugs. Moreover, these drugs, including also thiopental sodium and barbiturates, may be given intravenously during the anesthetic. To obtain relaxation, one of the muscle relaxants may be given. Addition of these drugs will allow a greater concentration of oxygen and thus minimize the danger of anoxia which is so apt to develop in nitrous oxide anesthesia.

Diffusion anoxia may develop after nitrous oxide anesthesia because the pulmonary alveoli and blood contain nitrous oxide, and, with the first inhalation of room air, nitrogen begins to diffuse into the blood and nitrous oxide into the alveoli. Since nitrous oxide is more soluble in blood, the amount of this gas available for diffusion outward into the lung is greater than the amount of nitrogen replacing it in the blood. This results in a net gain in the gas volume of the lung, and the lung merely expels gases instead of expanding. To prevent this diffusion anoxia, a high concentration of oxygen should be maintained at the end of administration of the anesthetic as the nitrous oxide is being eliminated.

Ethylene. This gas (C_2H_4) is only slightly more potent than nitrous oxide, but it has a slightly pungent, disagreeable odor and it is explosive. It is not used extensively.

Cyclopropane. This gas is a much more powerful anesthetic agent than nitrous oxide or ethylene; it produces greater relaxation and is effective with a much higher concentration of oxygen. It is thus particularly useful when respiratory disease is present. Since it is explosive, it cannot be used in the presence of a cautery. It slows the heart rate through a mechanism which is poorly understood. It will occasionally produce cardiac arrhythmia. It is particularly valuable as a substitute for ether when the operation requires muscular relaxation; however, relaxation is not as complete as with ether. The muscle relaxants (see page 209) remedy this deficiency by producing sufficient relaxation to perform any celiotomy. It is a very good anesthetic for patients in hemorrhagic shock because of its tendency to increase blood pressure.

Divinyl Ether. This volatile liquid is flammable and deteriorates on exposure to air. It has a narrow margin of safety. Divinyl ether

has a rapid action with a short induction period and quick recovery. Its use has been limited largely to operations requiring but a short period of anesthesia because, with prolonged use, there is danger of renal and hepatic damage. It may be used as an induction agent to be followed by open drop ether.

Chloroform. Chloroform ($CHCL_3$) was first used in Scotland by Sir James Y. Simpson in 1847 and thus was really introduced contemporaneously with ether. Chloroform is a volatile liquid and is administered by inhalation of its vapor as is ether. It produces rapid anesthesia, excellent relaxation, and is not flammable; however, its toxic effects on the liver, its narrow margin of safety, and the considerable danger of causing cardiac arrest have made it unpopular in this country.

Allied to chloroform is *ethyl chloride,* a still more volatile liquid which evaporates so rapidly that it is used (frequently unsuccessfully) as a local anesthetic by freezing the sensitive skin over an abscess. Sprayed over or dropped upon a gauze mask as an inhalation anesthetic, it produces a rapid anesthesia, but, with such a narrow margin of safety, it cannot safely be used for operations which last more than a few minutes.

Barbiturates. Thiopental (pentothal sodium) and thiamylal (surital sodium) are short-acting derivatives of barbituric acid and induce anesthesia by intravenous administration. Pentothal sodium produces an immediate, though short-lasting, anesthesia, i.e., 10 to 20 minutes. The duration of anesthesia may be extended by giving intermittent injections as required. The total dose varies greatly (1 to 3 gm.) depending upon the duration of the anesthesia, the type of patient, and the degree of preoperative narcosis. Great care must be exercised to place the needle in a vein and not an artery because injection into an artery has been known to produce gangrene of an extremity. Respiratory depression must be avoided by watching the patient's respiration. These drugs have the advantage of being safe in the presence of cautery. They are used for short operations, for operations which do not require deep anesthesia, for operations on patients in whom a gas–oxygen or other inhalation anesthetic is inconvenient or inadvisable, and for such procedures as incision of abscesses, reduction of fractures, and amputations. They are also widely used as a method of "induction" preliminary to other methods, including intratracheal anesthesia. Some anesthetists combine them with muscle relaxants for laparotomies. In the hands of competent anesthetists, they have proven useful and comparatively safe. Since these drugs are detoxified by the liver (12), action is prolonged; their margin of safety is probably less in patients with hepatic disease. Also, these drugs can produce a serious drop in blood pressure.

Avertin. This drug is usually considered a basal anesthetic agent and, formerly, was given as an enema in the patient's room. It is no longer employed because of its toxicity and depressant action on blood pressure. It produces a complete unconsciousness which, with large doses, lasts several hours. Though total anesthesia is not desirable, the amount of ether or gas necessary after its use becomes considerably diminished.

Muscle Relaxants. In abdominal operation, muscle relaxation is necessary to allow easy access to various organs and operations upon them. The first of these agents to be used (1940 to 1941) was d-tubocurarine (curare). Numerous others including succinylcholine, dimethyl-d-tubocurarine iodide (Metubine), decamethonium bromide (Syncurine), and gallamine triethiodide (Flaxedil) are available. These drugs are not anesthetic agents but produce their effects by relaxation and paralysis of skeletal muscle, presumably by preventing acetylcholine from reaching the receptor area of the muscle cell membrane. The drugs used most commonly are d-tubocurarine and succinylcholine; their clinical dosages are approximately 18 and 30 mg., respectively; the time required for action is 90 to 150 seconds for the former and 30 to 75 seconds for the latter. One of the disadvantages of succinylcholine is its tendency occasionally to produce apnea.

The effects of these drugs last from 40 to 50 minutes; after lapse of this time, the drugs may be repeated in smaller doses. They can be used with any anesthetic, but, if used with ether, the dosage must be greatly reduced, because the effects of these two drugs are synergistic. Overdosage results in respiratory paralysis which must be treated with artificial

respiration. Prostigmine is a physiologic antidote.

REGIONAL ANESTHESIA

A common misconception about local anesthesia is that it involves no danger. Actually the hazards are far from negligible; although they are uncommon, one should be thoroughly familiar with the various toxic reactions before using local anesthesia. The *toxic effects of local anesthetic drugs* are too often regarded as mere nervousness. Actually they consist of both circulatory and neurologic manifestations; e.g., there may be nervousness, talkativeness, excitability, delirium, convulsions, weakness, faintness, palpitation, nausea, vomiting, pallor, falling blood pressure, slow or fast pulse, loss of consciousness, complete circulatory collapse, and death. Many of these effects are due to sensitivity (allergy). The possibility of a toxic reaction may be predicted by noting any history of idiosyncrasy and minimized by use of the smallest volume and lowest concentration required, by use of epinephrine to reduce the rate of absorption when used for infiltration, by slow injection, and by avoidance of intravascular injection. Neurologic reactions may be minimized by preliminary administration of a barbiturate, but this has no prophylactic effect on circulatory reactions. Should a toxic reaction occur, the maintenance of respiration is mandatory—by artificial respiration if necessary. Administration of a barbiturate intravenously may be employed to control convulsions. Epinephrine may be given cautiously for circulatory collapse (low blood pressure, bradycardia, or, less commonly, tachycardia) if a reaction to it can be ruled out. Since the potency and toxicity of the various drugs differ considerably, it is not safe to substitute one for another without being thoroughly acquainted with the peculiarities of each. It is also important to always use similar technic, particularly in spinal anesthesia, because injudicious variations from the procedure with which one is familiar may result in numerous complications, some of which may be disastrous.

Cocaine. This agent is useful in solution (5 to 10 per cent) to anesthetize mucous membranes, notably in the oral and pharyngeal cavities. It need not be injected for this purpose but merely applied to the area with a pledget of cotton. It is also used to anesthetize the conjunctiva, urethra, and bladder. In preventing the gag reflex during the passage of a stomach, duodenal, or nasal tube, it finds a useful place. It has the disadvantage of being toxic and habit forming and, for hypodermic use, has been superseded by a related drug, procaine hydrochloride.

Procaine Hydrochloride (Novocain). Procaine is perhaps the most widely used of the local anesthetics. It is an ester of para-aminobenzoic acid and diethylaminoethanol and was synthesized by Einhorn in 1905. The advantages of procaine are low cost, low toxicity, and ease of sterilization without danger of change or loss of action. The disadvantages are its short action and lack of topical activity. It is used in concentrations varying from 0.25 to 2 per cent.

Lidocaine (Xylocaine). This is particularly useful because of its rapid onset of action, its greater spreading ability, and its longer duration of action.

Other Agents. Numerous *other agents* are available for local anesthesia. *Dibucaine hydrochloride* (*Nupercaine hydrochloride*) is also useful when prolonged anesthesia is desired. Its greater toxicity is neutralized by the low concentration needed for anesthesia. *Pontocaine hydrochloride* is similar to procaine but is more effective on mucous membranes; it is also used in spinal anesthesia. *Metycaine hydrochloride* is used for spinal anesthesia, its action being slightly longer than that of procaine.

METHODS OF ADMINISTRATION OF LOCAL ANESTHETICS. These agents may be given in numerous ways.

1. Local *infiltration* (Fig. 4) is perhaps the method most commonly used; it is begun by forming a wheal in the skin using a hypodermic needle which is introduced into the derma. A 0.5 to 1 per cent solution is usually used. Anesthesia is due in part to the pressure on the nerve endings destroying their sensitivity and thus may be achieved with plain water which, however, loses its effect as soon as the wheal disappears (5 to 10 minutes). Procaine hydrochloride has, in addition, an anesthetic effect on the nerves themselves, and hence its effect lasts longer (30 minutes).

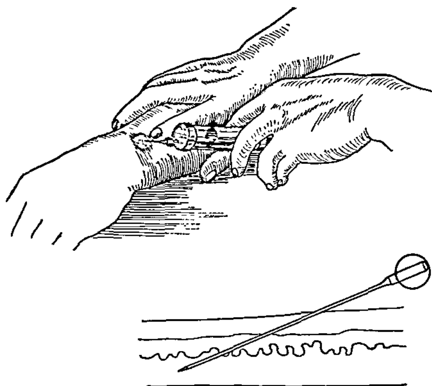

Fig. 4. The local infiltration of Novocain. Note the formation of a wheal in the skin. This is produced by injecting the agent into the derma as shown in the lower insert. This wheal establishes a painless portal of entry for the further injection of Novocain.

Epinephrine (5 drops of a 1:1,000 solution to each 100 ml.) causes vasoconstriction and thus prolongs anesthesia by diminishing absorption. Once this anesthetic portal of entry is made, the rest of the process is painless and simply consists of completing the infiltration of the skin and operative field.

Procaine may also be injected into the hematoma at the site of a fracture (10 to 30 ml. of a 1 per cent solution) and often achieves sufficient anesthesia to enable satisfactory reduction, especially of the small bones such as the radius and ulna.

2. *Block anesthesia* or *nerve-blocking* can be used to produce anesthesia in almost any part of the body. A solution of 1 to 2 per cent procaine hydrochloride is usually used in adults; a few milliliters are injected in direct proximity to the nerve supplying the area to be anesthetized. Brachial plexus block is particularly useful in certain patients with fractures and other injuries of the upper extremity. This important application of local anesthesia was discovered by Halsted, according to an award made to him by the American Dental Society in 1922. Bilateral block of the intercostal nerves will give fair relaxation for laparotomies. Splanchnic anesthesia, obtained by infiltration of the prevertebral tissues of the upper abdomen (by the anterior or posterior route) so that the splanchnic fibers and celiac plexus are blocked, is still used in parts of the world with limited facilities but is seldom employed here because other more satisfactory agents are available.

3. *Spinal anesthesia,* properly given in selected patients, has achieved a widespread use in recent years and competes successfully with the various forms of general anesthesia in certain clinics and in certain operations. The great advantage of a successful spinal anesthesia is the flaccid paralysis it produces which, in robust, muscular, and obese individuals, means an even more complete relaxation of the abdominal muscles than follows ether narcosis. For difficult intraperitoneal operations this is particularly valuable. Spinal anesthesia, moreover, does not produce a loss of consciousness, a feature which many patients and anesthetists prefer. Spinal anes-

thesia is also useful diagnostically in peripheral circulatory disease.

One of its disadvantages is its relative lack of control; once the full dose is given, its effects follows, and there is no method of stopping it as one may do with inhalation anesthetics. This defect can be overcome by "continuous" spinal anesthesia which is achieved by introducing a catheter into the subarachnoid space and introducing procaine in small doses as needed. Spinal anesthesia paralyzes the autonomic as well as the spinal nerve fibers, and, while the resultant fall of blood pressure may be minimized, its deleterious action on the circulation makes it dangerous in patients susceptible to circulatory impairment such as low blood pressure, heart disease, and late low intestinal obstruction. The danger of producing injury to the spinal cord itself is remote. Permanent neurologic signs and symptoms have been observed following spinal anesthesia, but they are usually related to errors in technic. Listed in order of increasing duration of effect, the drugs commonly used are procaine hydrochloride, pontocaine hydrochloride, and nupercaine hydrochloride. With the exception of nupercaine hydrochloride, the effect of the drug nearly always wears off in from one to two hours. The effect of nupercaine hydrochloride lasts much longer.

Many methods of administration have been reported, but the one commonly used consists of removing 2 to 5 ml. of spinal fluid by lumbar puncture, dissolving in it 50 to 200 mg. of specially pure procaine hydrochloride crystals, and reinjecting the fluid after solution is complete. The amount of fluid injected, the dose of the drug, the rapidity and force with which the fluid is reinjected, the specific gravity of the fluid, and the slope of the patient's spine determine the level and, in part, the duration of the anesthesia. The dose of pontocaine hydrochloride is about 8 to 20 mg. Nupercaine hydrochloride is usually used in a 1:1,500 solution of which 8 to 20 mg. are given.

In a follow-up study made by Vandam and Dripps (13) of 8,460 individuals given 10,098 spinal anesthetics, 0.8 per cent had residual signs or symptoms of numbness following their anesthesia. In the vast majority of patients, the numbness was restricted to the lumbar and sacral areas of the body. Most of the complaints had disappeared after six months. There were no other neurologic sequelae such as transverse myelitis, meningitis, or arachnoiditis.

4. *Epidural anesthesia* is obtained by blocking the spinal nerves in the epidural space just after they emerge from the dura and before they pass into the intervertebral foramina. The injection may be made at various levels—thoracic, lumbar, and caudal. The needle is introduced slowly between the spines of the thoracic or lumbar vertebrae through the interspinous ligament, and still more slowly through the ligamentum flavum, stopping short of the dura limiting the subarachnoid space. The chief advantage of a thoracic or lumbar epidural anesthesia is the fact that a segmented analgesia can be obtained. The chief disadvantage of epidural anesthesia is its uncertainty and technical difficulty; occasionally anesthesia is not obtained.

Caudal (sacral) anesthesia is a type of epidural anesthesia. It is useful in operations about the external genitalia and anus. It is administered by inserting a needle into the sacrococcygeal notch through the skin and ligament into the epidural space (Fig. 5). About 30 to 40 ml. of a 1 per cent procaine hydrochloride solution can be injected at this site. This bathes the emerging sacral nerves and, in most instances, produces a satisfactory anesthesia of the saddle type. The great disadvantage is its uncertainty; in 10 to 20 per cent of cases, anesthesia is not produced. The anesthesia is more certain if several of the sacral foramina, particularly the second, are also injected with about 5 ml. of 1 per cent procaine hydrochloride. Such procedures as hemorrhoidectomy and cystoscopy can be performed with this type of anesthesia. In recent years xylocaine, pontocaine hydrochloride, and cyclaine have become perhaps the three most popular anesthetics used for caudal anesthesia (14).

5. *Therapeutic nerve block* should be included under local or regional anesthesia and has many applications as discussed in other parts of the text. Indeed, use of alcohol instead of procaine often leads to permanent interruption of pains and spasm; the disad-

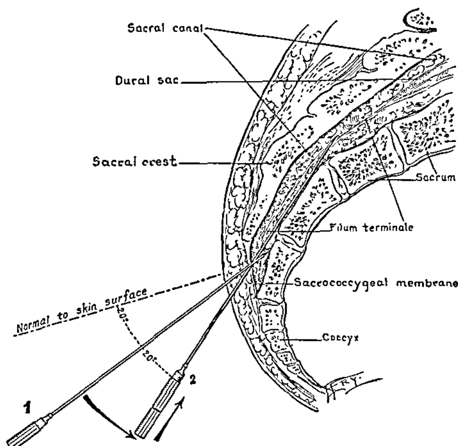

Fig. 5. Caudal block. Longitudinal cross section of the lower vertebral column is shown, including the manner by which a local anesthetic is introduced into the extradural space. After piercing the sacrococcygeal membrane, the needle impinges on the anterior wall of the sacral canal and passes from position 1 to position 2 in direction of the arrow. (From Labat. Regional Anesthesia, W. B. Sunders.)

vantage is that occasionally a painful neuritis rather than anesthesia follows.

Freezing. A momentary anesthesia can be brought about by freezing the part to be incised with an ethyl chloride spray; however, this is followed by mild pain after the frozen tissue thaws out. Another disadvantage is that freezing hardens the tissue and makes incision a little more difficult; this, however, may be obviated by using a sharp bistoury knife. Freezing has the great advantage of simplicity and speed but finds almost its sole use in very superficial abscesses when the skin is still too sensitive to be incised without anesthesia. When the abscess is deeper and the overlying skin uninvolved, it is far better to infiltrate with procaine or to resort to general anesthesia.

Refrigeration in Anesthesia. This procedure (originally utilized by Allen) is applicable chiefly to the lower extremity. In reality it is not a type of anesthesia but should be classified as a method of preoperative preparation. Ice bags are placed around the leg proximal to the site of operation. After one-half hour, the area is numbed sufficiently to tolerate the application of a tourniquet (two layers of half-inch rubber tubing). The limb is then packed in chipped ice from above the tourniquet to the toes. After several hours (two to four), when the temperature of the limb has dropped to within a few degrees of the freezing point, there is complete analgesia; amputation or other operations on the extremity can then be performed. The ice is, of course, removed, but the tourniquet is left on until near the end of the operation. This method of anesthesia is laborious, and its application is limited. It may be of advantage in cases of gangrene or severe injury when shock is pres-

ent. However, Large and Heinbecker (15) have shown that refrigeration results in retardation of healing of tissue so treated.

CONTROLLED HYPOTENSION IN ANESTHESIA

In an effort to reduce loss of blood during operation, hypotension is occasionally induced deliberately, particularly in operations where excessive hemorrhage is expected or in procedures where bleeding interferes with the operation, e.g., brain tumors. It is hoped that the operation will be shortened by decreasing blood loss. Originally, hypotension was induced by spinal anesthesia. More recently sympatholytic drugs, e.g., thiophanium d-camphorsulfonate (Arfonad) and hexamethonium, have been used for this purpose. Under such circumstances, the hypotension is essentially neurogenic without peripheral constriction and perhaps under better control than when spinal anesthesia is used. There is no evidence that the oxygen supply to the tissues is hampered, but coronary blood flow is probably decreased; however, the hazard of reduced coronary flow is lessened to a great extent by the diminished workload required of the heart during hypotension.

The drugs are given intravenously by drip until the systolic pressure reaches the desired level, usually between 70 and 80 mm. Hg. Discontinuance of the drug results in a rapid return of pressure to normal within a few minutes. While the pressure is being maintained at levels mentioned above, the patient must be kept in a horizontal position, since elevation of the head might result in dangerous cerebral ischemia. If vasopressin drugs are indicated because of failure of the pressure to return to normal, the dose must be kept extremely small, because the usual dose may cause a dangerous rise in blood pressure (16).

HYPOTHERMIA AS ANESTHESIA

To a great extent, the needs of intracardiac surgery have been responsible for the development of hypothermia in anesthesia. With hypothermia, the surgeon can interrupt the blood-pumping function of the heart for longer than three or four minutes, which is the safe limit in a patient with a normal body temperature. As hypothermia reduces body metabolism, even the brain can survive cessation of circulation for 20 minutes or more, thus allowing the surgeon time to repair defects in the open heart.

McQuiston (17) was one of the first to demonstrate that mild hypothermia (1 to 3° C.) exerted a protective effect in the operative management of cyanotic heart disease. During the next few years, the pioneer work of Bigelow (18), Swan (19), and others demonstrated that hypothermia of several degrees (down to 28° C.) is helpful in cardiac surgery.

Body temperature can be lowered by a variety of methods, such as immersion in ice water, wrapping in "cold" blankets, and direct cooling of blood. With a reduction of body temperature, the heart rate slows, the blood pressure falls, respiration becomes slower, and cardiac output diminishes. Anesthesia is needed for the induction of hypothermia; however, once the temperature drops below 28° C., anesthesia is sufficient to allow operative procedures without any other agent. However, at this temperature ventricular fibrillation becomes a hazard and is increasingly common.

TOXICITY AND DANGERS OF ANESTHESIA

Anesthesia implies a deliberate, artificial, physiologic disturbance. Loss of consciousness, loss of response to painful stimuli, and loss of muscular tone are obvious examples of the disturbances of physiology which are deliberately produced to facilitate surgical procedures. Unfortunately many undesirable effects are likely to be produced at the same time.

Respiratory disturbances include depression, obstruction, reduction of protective cough reflex, and increased secretion. The gastrointestinal system may be affected with resultant nausea, vomiting (with the possibility of aspiration of vomitus), increased salivation, and altered intestinal motility. If vomiting persists in the postoperative period, it interferes with normal nutrition, results in loss of fluids and chlorides, and may seriously affect the patient's convalescence.

Serious *circulatory disturbances* may result

from anesthesia. There may be circulatory depression contributing to shock, changes in pulse rate, changes in the distribution of blood, and sudden cardiac arrest.

Beside the obvious effects on the *nervous system* (loss of consciousness, loss of reflexes) there may be other serious disturbances. Excitement may result in injury to the patient or others. Convulsions may occur. These are usually associated with increased body temperature (hot weather, heavy drapes) and carbon dioxide excess. The autonomic nervous system is also affected. Some agents stimulate the sympathetics while others stimulate the parasympathetics. The size of the spleen, an important consideration in splenectomy, may be altered. Ether contracts the spleen and is, therefore, the agent of choice for splenectomy.

The *acid-base balance* is disturbed usually toward the acid side. Not only do some agents cause an acidosis, but also respiratory depression and the probability of some rebreathing of the expired atmosphere result in accumulation of carbon dioxide and further acidosis.

Liver function is depressed by most anesthetic agents, particularly chloroform, and by oxygen want. Recovery is usually rapid, but in cases with preoperative liver damage the additional impairment may be serious. The damage may be minimized by preoperative dietary preparation designed to increase the carbohydrate and protein and reduce the fat content of the liver. Also, the use of a high oxygen atmosphere during anesthesia is helpful. Based upon a study of liver function tests, Boyce (20) noted that there was a depression of liver function following practically all anesthetics. Of the various agents tested by him, this depression was noted following chloroform, spinal anesthesia, ether, and ethylene with a degree equivalent to the order named. He explained the serious depression following spinal anesthesia on the basis of the fall in blood pressure resulting in a decreased oxygen supply to the liver. Although cyclopropane was not tested, Boyce was of the opinion that it would be followed by a minimal amount of hepatic depression because of the high oxygen content of the gaseous mixture used. Maddock and associates (21) approximated the degree of hepatic injury following anesthesia by determining the glycogen content of the liver. In these experiments, the average glycogen content for the normal liver was 3.96 per cent, whereas it was 3.15 per cent following spinal anesthesia. The glycogen content in patients with normal livers was raised to an average of 5.03 per cent by supplementary glucose feedings for 12 hours preceding operation. However, the operation itself will naturally be a factor in depressing liver function.

Kidney function is also depressed by anesthetics. A decrease in glomerular filtration (persisting for a few hours to a week) has been noted following anesthesia induced by ether, cyclopropane, and avertin. The decreased function may be related to the amount of blood lost and the severity of the blood pressure fall. Serious acidosis may result from renal impairment.

Another physiologic disturbance produced by anesthesia which is too often overlooked is the *impairment of heat regulation*. In hot weather the patient may develop hyperpyrexia which may contribute to shock, disturbed metabolism, increased oxygen demand, and in some cases to the development of convulsions. This is particularly true of operations upon patients with hyperthyroidism. In general, such operations should be performed in hot weather only when an air-conditioned room is available for the operation and during the postoperative course. In hot weather the amount of sterile drapes should be held to a minimum; in fact, if the patient appears warm, his legs should be uncovered and cold wet packs applied.

Many of these disturbances may result from local or spinal anesthetics. Convulsions, circulatory collapse, and oxygen want may be cited as examples.

Only the well-trained physician anesthetist collaborating with the rest of the surgical team can appreciate all these disturbances of physiology and, by the judicious choice of anesthetic agents and technics, minimize their seriousness.

Explosion hazards are numerous in anesthesia. Of the common inhalation anesthetics, only nitrous oxide and chloroform are non-explosive. Obviously, rectal avertin, intravenous and regional anesthetics are not explosive. The source of ignition may be artificial, e.g., cautery, flame, or spark from electric

apparatus, or it may be a spark due to static electricity. Electric apparatus should be designed to avoid unexpected sparks, and, when a known source of ignition (e.g., cautery) is to be used, the anesthetist should avoid explosive agents. Static sparks are more difficult to anticipate and are an ever present hazard. High relative humidity, proper (moderately conductive) flooring, and avoidance of wool blankets can reduce the danger. Nevertheless, any moving person may accumulate a static charge which, if discharged near an explosive anesthetic, may result in a fatality. Nylon uniforms tend to create static electricity and should be prohibited. Most important is the fact that rubber- or composition-soled shoes insulate the wearer and promote the accumulation of static electricity. *Only leather-soled shoes (or those with specially designed conductive soles) should be worn in the operating room.* Rubber heels are not prohibited.

The *death rate* from anesthesia has recently been studied by Beecher and Todd (22). In a report containing data from 559,548 surgical patients in 10 different institutions between 1948 and 1952, they noted an over-all rate of 1 in 1,560 patients. Deaths were disproportionately higher in the first decade of life and in the latter decades. Since more than one agent was given so often to the patient, it was difficult to obtain an accurate rate for each of the drugs used during this period. However, the assignment of deaths to the various agents, to the best of the ability of the workers contributing to this study, revealed the highest death rate for curare, being 1 in 370 patients or six times as high as the control series of 1 in 2,100. The lowest rates were with regional and spinal anesthesia, being 1 in 2,330 and 1 in 1,780 respectively. The rate for ether was 1 in 820, approximately the same as for cyclopropane.

COMPLICATIONS DURING ANESTHESIA

Under this heading will be discussed some of the more important complications related primarily to the operation. Since the manifestations of these complications are usually detected readily by the anesthesiologist, it is essential that he be watchful of their development so that prophylactic and therapeutic measures may be instituted early. In fact, the anesthesiologist should keep the surgeon informed of any evidence of deterioration of the patient's physical condition so that the surgeon may modify or terminate the operation as indicated.

Aged and poor risk patients are slightly more prone to develop complications from anesthesia than are other patients. Age itself is no contraindication to anesthesia, but complicating diseases may indicate certain anesthetics to be preferable to others, as discussed in detail by Adriani (23).

Shock is one of the most common complications occurring during major operations and is detected by fall in blood pressure, tachycardia, pallor, and sweating. *Transfusion reactions* occurring during operations are obviously very serious and should be detected as early as possible; important manifestations are cyanosis, unexplained cardiac irregularity, excess oozing of blood from the operative site, hemolyzed serum or plasma, and hemoglobin in the urine. Development of *atelectasis* during operation is not uncommon; it may be detected by tachycardia, hyperpnea, cyanosis, lack of movement on the affected side, and other manifestations commonly observed. Fortunately, it can usually be corrected promptly by aspiration of the obstructing debris from the bronchus leading to the affected lobe or lung.

Cardiac irregularities are particularly common during operations on the heart or lungs. Intravenous procaine hydrochloride is quite effective in prophylaxis and treatment, but its use is so often followed by serious hypotension (24) that therapy should probably be limited to treatment and not prophylaxis. Procaine amide has been reported effective by Rovenstine and associates (25) in the ventricular tachycardia and extrasystoles occurring in patients undergoing thoracic operations, particularly under cyclopropane anesthesia. They found the drug useful in prophylaxis as well as in therapy.

SYSTEMIC REACTION TO TRAUMA

John M. Howard

Every serious wound produces certain nonspecific systemic effects on the body as a whole, as well as disturbances in organs or systems far removed from the wound. These remote results of injury often prove of greater consequence in the recovery of the patient than the wound itself. Certain systemic effects of a severe wound are obvious, such as pain and fever, anemia from loss of blood, prostration, immobility, and anorexia. In themselves, these are responsible for many changes in the body as a whole. Such other consequences as shock, metabolic changes, the so-called pituitary-adrenal reaction, changes in cell permeability, and hepatic, renal, and gastrointestinal impairment are also important. It will be the purpose of this chapter to discuss these systemic and outlying effects of injury with special reference to possible therapy designed to combat their potential harmful results while at the same time to evaluate and recognize their beneficial influences.

HISTORICAL SURVEY

It must have been obvious to the earliest observers that the seriously wounded frequently became ill and many died, either early or late, for reasons not directly connected with the wound. The earliest biochemical evidence of a serious metabolic disturbance after a severe wound was noted by Malcolm (1) who, in 1893, found a large increase in the urea output in the urine. This evidence of an increased destruction of tissue protein was observed in 1909 by Shaffer and Coleman (2), in studies on typhoid fever.

It was Cuthbertson (3) however, who, in 1929, first studied in detail what he called the "catabolic response to injury" and even attempted to explain its significance. He believed that it was a mechanism on the part of nature to provide certain nutritional elements necessary for life from the breakdown of protein tissues during periods when the animal was unable to obtain exogenous nourishment. This process, later given the more elegant name of gluconeogenesis, rapidly breaks down normal tissue protein to yield amino acids, of which many may be utilized as such and others are deaminized to provide energy. The increased output of nitrogen in the urine, however, not only originates from the catabolism of normal protein tissue but, in accidental and operative trauma, there is a breakdown of damaged protein tissue and of extravasated plasma protein and hemoglobin. Other changes, especially in salt metabolism, were later observed. Mention should also be made of the work of Walter Cannon (4) who carefully studied the systemic effects of rage, fear, pain, and other emotions which are, of course, known to accompany injury of various kinds including tissue trauma.

The discovery that the adrenal cortex plays an important role in the systemic response of the body to injury is more recent. Quite early, repeated observations showed that animals deprived of their adrenal glands either died or, when kept alive by such means as high salt intake, were unable to withstand the effects of even slight trauma or moderate changes in environmental temperature. In

such animals, stress of any kind produced profound systemic disturbances. Slight hemorrhage was followed by severe shock. Addison's disease in humans produced a similar clinical state and was also due to destruction of the adrenal cortex. Only by administering whole adrenocortical extract in sufficient doses to adrenalectomized animals could they withstand even mild stimuli which might be considered normal since they are being continually overcome. To a similar but lesser extent, hypophysectomy had the same effect. That the adrenals were normally stimulated by harmful influences seemed a logical inference. Selye (5), who has done much to advance this idea, called this adrenocortical response a "stress" or "alarm reaction," believing that it represented a defensive mechanism to be compared with a "call to arms." He found, among other things, that persistent stress in animals led to enlargement of the adrenal gland. The role of the pituitary gland was suggested when it was found that the adrenal changes failed to occur after hypophysectomy. Later, the isolation and use of ACTH (adrenocorticotropic hormone) confirmed the importance of the pituitary in the stress reaction, for it, like stress, produced evidence of adrenocortical stimulation in animals and in humans. This brings us back to the work of Walter Cannon (4), who showed that the effect provoked by rage, fear, and pain, was due to the release of epinephrine from the medulla of the adrenal. It was later shown that epinephrine itself directly or indirectly stimulates the pituitary and thereby adrenocortical activity. For example, Long and his co-workers (6) have demonstrated that the subcutaneous injection of epinephrine produced a fall in the vitamin C content of normal rat adrenal cortex similar to that provoked by certain injurious agents, but did not when given three days following hypophysectomy. A similar result was obtained by Sayers and Sayers (7) with experimental hemorrhage. From these and other studies, it would seem that the adrenal cortex, presumably by way of the pituitary, is provoked to hyperactivity by many kinds of harmful stimuli, a response which is now believed to be an important part of the systemic reaction to injury, or indeed of damage or stress of other kinds including "psychic trauma."

From the purely clinical point of view, many studies have revealed the nature and extent of the systemic nonspecific effects of injury, particularly of planned operations. Perhaps the earliest was initiated by a series of reports by Leriche, based on what he called "La Maladie Postoperatoire." This early work was summarized in a monograph with that title (8) and by a more recent report (9). During World War II, many biochemical and metabolic studies were made in injured soldiers (10, 11, 12). Extensive metabolic studies of civilian patients during postoperative convalescence were reported by Cole and his co-workers (13), which has added much to our knowledge. A brief study of surgical convalescence by Elman and Akin (14) contains observations regarding nutrition, psychogenic factors, and physical factors. More recently, in a monograph containing excellent data on many carefully observed postoperative patients, including volunteer controls, Moore and Ball (15) have continued the work and stimulated further interest in this field.

The most recent and extensive clinical study of the systemic effects of injury was that of a surgical research team set up by the United States Army during the latter part of the Korean conflict. The extensive findings have been summarized in four volumes from the Walter Reed Army Medical Center (16). Much of these data will be used in the following discussion.

PITUITARY-ADRENAL REACTION

The concept of a pituitary-adrenal reaction as a nonspecific, systemic response to injury is recent, stimulated largely during the past decade by epoch-making chemical research on the hormones of the two glands. This new field has already yielded potent therapeutic agents and many intriguing ideas, which may completely alter our concept of disease and of therapy. In the following discussion, an attempt will be made to summarize the bare essentials of this vast amount of knowledge as it applies to the treatment of the injured, realizing that much is unknown and that even what is supposedly known will change as in-

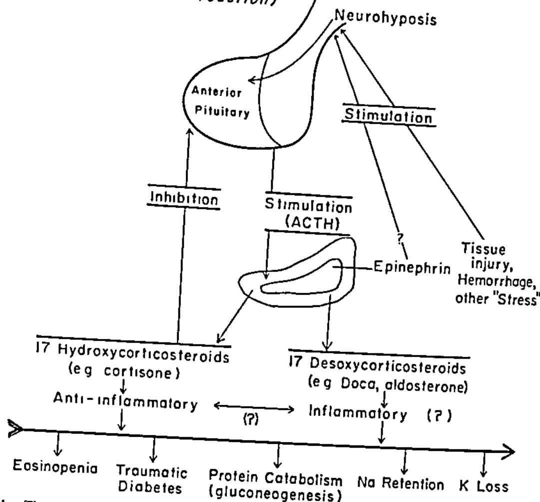

Fig. 1. The pituitary-adrenal reaction. Presumed pathways of the "alarm reaction" diagrammatically represented. The balanced inflammatory-anti-inflammatory action of the groups of corticoids is largely theoretical or speculative at the present time. The variations in the physiologic action of the two groups of corticoids are arbitrarily listed at the bottom. The heavy arrow is supposed to indicate quite grossly the relative action of the two groups.

creasing contemporary research adds more information. This tentative nature of our knowledge applies especially to the probable pathways of the pituitary-adrenal reaction to injury as illustrated in Figure 1.

History. The vital function of the adrenal glands was known to Brown-Sequard and his followers when it was noted that bilateral adrenalectomy was incompatible with life for more than a few days or weeks in mammals, for only a few hours in birds. That the adrenals maintain life by secreting essential hormones was shown by Rogoff and Steward, Swingle and Hartmann, and others when lipid and aqueous extracts of the glands prolonged the life of adrenalectomized animals and, in fact, improved the symptoms in patients whose adrenals had been destroyed as in Addison's disease. But the greatest advance came when the individual hormones of the adrenal cortex began to be isolated, identified, and even synthesized. Among the many investigators in this field, three chemists, working simultaneously in different parts of the world during the period preceding World War II, were largely responsible for the beginning of this new knowledge. They are Kendall, Reichstein, and Wintersteiner; the first two were awarded the Nobel prize for their discoveries.

Reichstein, a Swiss organic chemist, having gathered tons of beef adrenals, made a sys-

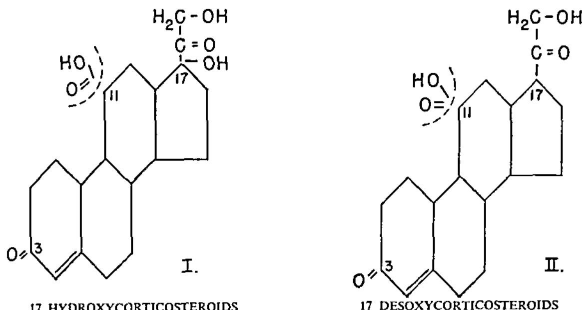

Fig. 2. Adrenocortical hormones. On the left is represented the group of steroids notable for its anti-inflammatory action, influence on carbohydrates and protein metabolism, and beneficial effect in shock due to adrenocortical insufficiency. By contrast, on the right is the group notable for its influence on salt metabolism, hence sometimes called mineral corticoids.

Group I. General formula for free 17-hydroxycorticosteroids, often shortened to 17-hydroxycorticoids or abbreviated as 17-OHCS. Note the OH radical at the 17 position, characteristic of this group. The grouping at the 11 position is of special significance; the three possibilities are illustrated. Using the Kendall classification, Compound E or cortiscone has a keto (oxygen) radical at this point, Compound F or hydrocortisone an hydroxy radical, Compound S has nothing (desoxy). The latter has little clinical importance. This group of corticoids are best measured chemically (at the present time) by the Porter-Silber (P-S) reaction.

Group II. General formula for free 17-desoxycorticosteroids, often shortened to 17-desoxycorticoids or abbreviated as 17-desoxy-CS. Note that they differ from 17-OHCS only in the absence of the OH radical at the 17 position, hence the name. The three variations at the 11 position are the same as above, the Compounds being A, B, and D respectively. Only Compound D is important clinically, with no oxygen (desoxy) at the 11 position. It is well known as DOC, the abbreviation of desoxycorticosteroid, or as DOCA, the acetate salt. The 17-desoxycorticosteroids are not clinically measurable as such, but can be determined by subtracting the P-S value from the Mader-Buck reaction which measures both groups. Note in both groups the keto (oxygen) radical at the 3 position. This, with the double bond adjacent to it (called D4), is found in all biologically active free steroids.

tematic study of adrenocortical hormones which he isolated therefrom (17). He was able to identify 28, all 4-ring steroids, 24 with 21 carbon atoms, three with 19, and one with 18. Many of them have little practical interest and may perhaps have been artefacts during the long chemical manipulations. In addition to the many steroids characteristic of the adrenal, progesterone and estrone were also found. According to present knowledge, the important adrenocortical steroids (or, more simply, corticoids) may be classified into two groups, all having 21 carbon atoms, the 20 and 21 carbons being in the form of a ketol chain —C=O—CH_2OH at the 17 position (Fig. 2). Group I has an OH at the 17 position and is called, collectively, 17-hydroxycorticosteroids (17-OHCS); Group II has no OH at this position and is called 17-desoxycorticosteroids (17-desoxy-CS). Each group comprises at least three specific compounds differing only in the 11 position which may carry either a keto (O =), an hydroxy (OH —), or a desoxy (nothing). Kendall (18) called the three compounds in Group I, Compounds E, F and S;* in Group II, Compounds A, B, and D, respectively (Table 1). It so happens that Compound E,

TABLE 1. Adrenal Cortical Fraction

Group	Fractions	Chief Physiological Actions
I	17-Hydroxycorticosteroids E* Cortisone F Hydrocortisone S 11-Desoxy-17-hydroxycorticosterone Pregnisolon	These fractions produce the anti-inflammatory action in acute rheumatism and associated diseases. They increase the breakdown of tissue proteins to amino acids with resultant synthesis of glucose from the acids (gluconeogenesis). They result in the disappearance of eosinophils and lymphocytes Hydrocortisone is the chief fraction in the human and, having a greater water solubility, can be given intravenously.
II	17-Desoxycorticosteroids A Dehydrocorticosterone B Corticosterone D Desoxycorticosteroid (DOC) Aldosterone	These fractions result in the selective retention of water and sodium, and the selective excretion of potassium by the renal tubules. Aldosterone has a salt-retaining activity 10 times that of DOC.
	Androgen Estrogen Progesterone	Secondary sex characteristics

* This column represents Kendall's classification except for S which is from Reichstein.

popularly known as cortisone, and Compound D (dOC or dOCA, as the acetate) were easiest to synthesize and thus became available for clinical use long before the others. The newer ones are aldosterone, a 17-desoxy-CS, and the many derivatives of cortisone, a 17-OHCS, which will be discussed in more detail below.

The next chapter in the story of the pituitary-adrenal reaction was the identification and isolation of the adrenocorticotropic hormone, popularly known as ACTH from the many "tropic" hormones secreted by the anterior pituitary gland. The relation of the pituitary to the adrenal cortex had been known long before. Although hypophysectomy, unlike adrena'ectomy, was not incompatible with life, many of the effects of injury on the adrenal (e.g., hypertrophy, and depletion of vitamin C and cholesterol) did not occur after hypophysectomy. When it was finally found that ACTH stimulated the adrenal cortex, it was obvious that adrenocortical function was normally controlled by the pituitary. The secretion of adrenocorticoids was later shown to inhibit adrenocortical activity by decreasing ACTH production, thus providing a self-regulatory reciprocal mechanism characteristic of the relation of many other endocrines with the pituitary.

Next in the history of pituitary-adrenal reaction was the development of the concept that it represented a normal response of the body to such harmful exogenous stimuli as tissue damage, psychic stress, or even pronounced changes in environment. As described by Selye in 1947, the pituitary-adrenal reaction (5) represented a "call to arms"; hence the term "alarm reaction." This response, of course, was assumed to be beneficial, enabling the body to better resist the deleterious effects of injury. The pathway was through stimulation of the pituitary which, via ACTH, increased the output of adrenocorticoids. These corticoids themselves are known to provoke metabolic and other changes in the peripheral tissues similar to those observed following injury. Thus the metabolic changes following injury were assumed to be the result of, and indeed were called, the "alarm reaction." That this reaction was beneficial seemed obvious and was, of course, supported by the old observation that hypophysectomized or adrenalectomized animals, even when they remained alive, could not withstand the effects of even slight trauma or changes in environmental temperature unless protected by substitution endocrine therapy. This is also true of patients with Addison's disease. It is important

to emphasize, however, that the Addisonian patient may have no symptoms whatever while in a stable clinical state; his difficulty arises from the inability to resist even slight injury without developing serious peripheral shock and even death. All of this, however, still does not explain how the metabolic action of the corticoids helps protect the body against harmful exogenous stimuli. Little is really known of these metabolic changes, but some speculation may be mentioned.

That nature would provide a built-in mechanism for survival is axiomatic. Since survival demands a continuous supply of many substances for energy and other needs, it is clear that, in the absence of exogenous sources, it must use its own tissues. In an earlier stage of man's evolution, when the individual depended solely upon his own predatory and other activities for such exogenous nourishment, an accident or injury which resulted in enforced immobility made survival entirely dependent upon the extent to which his own tissues could supply these needs. Deprivation of intake, as in simple starvation, is compatible with survival for a variable period because these needs are met by protein and adipose tissue breakdown. Following injury, however, this simple process is apparently not rapid or extensive enough to meet the needs for existence and repair. It is not surprising, therefore, that the first and perhaps most important metabolic effect of injury to be observed was the increased breakdown of normal protein tissue. Such an action would, of course, yield a variety of metabolic, really nutritional, substances. The degree of this breakdown is measurable by the urinary excretion of nitrogen, which is known to rise two to four times above that in starvation alone. This phenomenon, often called the "catabolic response to injury," can also be provoked to some extent by both ACTH and cortisone. A more frequent name given to this phenomenon is gluconeogenesis, by which is meant the formation of glucose from tissue protein. It should be emphasized, however, that tissue protein breakdown yields more than amino acids which, on further breakdown, form glucose. Other substances are undoubtedly released which are also required for survival in the absence of any exogenous intake. On the other hand, there is little evidence that adipose tissue breakdown, which yields only energy, is increased during the alarm reaction. It is likely, however, that the mechanism for the formation of glucose is the most important action. This mechanism extends and augments the old and well-known release of glucose from hepatic glycogen following the increased secretion of epinephrine which, as shown by Cannon (4) just before the days of ACTH and cortisone, was part of the response to stress. Epinephrine provokes many other systemic effects now included in the alarm reaction. Since epinephrine is also secreted by the adrenal medulla, we seem to have traveled a sort of scientific circle, embracing a period of about two decades. This represents only a small segment of the vast amount of information which has accumulated during this time regarding the pituitary-adrenal reaction. Moreover, we are still in the dark as to the beneficial effects of the metabolic changes other than gluconeogenesis.

Because injection of cortisone and ACTH can, in the intact subject, provoke many of the metabolic results of injury, it is generally assumed that these metabolic disturbances are due to the peripheral action of the increased output of corticoid. This assumption, though widely held, must now be modified on the basis of recent observations made on bilaterally adrenalectomized patients maintained in a relatively normal clinical state with cortisone (19). Subsequent elective operations on these patients were found to be accompanied by the same metabolic changes as those produced by similar procedures in patients with intact adrenals. This would seem to indicate that the metabolic changes after operation may be primarily peripheral; i.e., they are the effects of operative tissue damage and anesthesia on the circulating corticoids, and not necessarily a manifestation only of increased adrenocortical secretion. While the increased secretion of pituitary and adrenal hormones is unquestioned, it may be that this action is merely secondary and regulatory. In any event, more study is needed of the effects of the peripheral tissues themselves on the metabolic conversion, reduction, and conjugation which the corticoids undergo not only under normal but especially in post-traumatic states. The greater influence

of the peripheral over the central changes is also suggested by observations on the anti-inflammatory action of the corticoids as discussed below.

The attempt to paint a simple picture of the alarm reaction also overlooks the fact that different steroids are secreted by the adrenal cortex (Table 1). Although it is true that hydrocortisone in the plasma, in man at least, is the most important member of the 17-OHCS group, there are various members of the 17-desoxy-CS group to be considered. Not only is the action of the latter different from that of the former, but each responds differently to the stimulus of injury and ACTH. For example, there is much evidence that the 17-desoxy-CS group may not even be under pituitary control and may have no balanced relationship with the secretion of ACTH, as is the case with 17-OHCS. Moreover, little is known of the extent to which the steroids may undergo conversion, one to the other, or be made inactive in various ways. Finally, it is already known that the physiologic effect of these hormones is certainly influenced by differences in their threshold of activity. For example, a large dose may produce an entirely different effect than a small one. This raises the question of whether the effect is really pharmacologic or physiologic. In actual practice, as much as 300 mg. of cortisone have been given per day—about ten times the amount normally produced, which rarely exceeds 30 mg. per day in an adult. Is the effect produced, therefore, due to the steroid itself, to its action in inhibiting pituitary function, or even to producing adrenocortical atrophy? Moreover, the length of time during which the hormone is administered is important. A very small dose of ACTH infused intravenously over a longer period will be a much more effective adrenocortical stimulant than a large dose administered during a short period of time.

Despite these factors, an attempt will be made to summarize present knowledge of this complicated pituitary-adrenal reaction under three headings, representing a somewhat arbitrary classification: (1) the *physiologic action* of the known corticoids; (2) the *changes in adrenocortical secretion* of these steroids as a result of trauma; and (3) the newest studies in the field, the *metabolic changes in the adrenocorticoids* once they leave the adrenal vein and enter the systemic circulation not only under normal but also under abnormal conditions of stress of various kinds, particularly operation or injury.

1. Physiologic Action of the Corticoids. The so-called *anti-inflammatory action* of cortisone and hydrocortisone and their derivatives is perhaps the most interesting of the physiologic actions of the adrenocortical steroids, and the one which first brought them to worldwide attention by showing their dramatic therapeutic application. This anti-inflammatory action was first noted experimentally by Selye (5), and aroused universal acclaim when cortisone was found to have a dramatic beneficial effect on the pain and the local inflammatory signs of rheumatoid arthritis. It is curious that, despite the increasing use of these steroids in many other conditions, the therapeutic pendulum in rheumatoid arthritis is now swinging back to the precortisone methods. It was soon found that this anti-inflammatory action was a local one. Indeed, dramatic benefits often followed when hydrocortisone was injected locally into inflamed tendons, joints, and bursae. Systemic effects were presumably responsible when a beneficial anti-inflammatory action was later found in a variety of conditions including hepatitis and thyroiditis. This systemic action was also supposed to explain the action of cortisone in certain specific bacterial inflammations, as tuberculous meningitis, pneumonia, and peritonitis. Although the effects were thought to be beneficial by greatly reducing the severe systemic manifestations, it was not clear whether this action lowered the response of the body to the invading agent, or suppressed the peripheral effects of the infection. Lowering of the body response would, of course, be ultimately harmful in reducing resistance. Present thinking, however, seems to point to the peripheral and the inflammatory action even when the steroid is given systemically. It might be compared to the use of antibiotics in the prophylaxis of infection of open wounds, in which the local effect was better subserved by letting the agents reach the injured tissues from the body side.

The local anti-inflammatory action of cortisone has been extensively studied by a

variety of technics. It seems generally agreed that this action consists of a decrease in the permeability of the inflamed capillaries and an increase in digestion and phagocytosis of exudate. This would certainly explain its local action in decreasing peritoneal adhesions and helping dissolve exudate in tuberculous meningitis, and even perhaps in combating anaphylactic shock. In anaphylactic shock, the increase in capillary permeability seems one of the decisive mechanisms, similar indeed to the local action of histamine. The lifesaving action of cortisone as a presumed anti-inflammatory agent is therefore thought to be that of counteracting this increase in capillary permeability.

The anti-inflammatory action of the corticoids is, of course, exerted to a pronounced degree only by the 17-OHCS group and not by the 17-desoxy-CS group. An intriguing theory was propounded by Selye, who felt that there was a reciprocal and balanced action between the two groups, one inflammatory and the other anti-inflammatory. Unfortunately for this idea, it is not supported by adequate evidence, at least as far as the presumed inflammatory action of the 17-desoxy-CS is concerned. It is true that, experimentally, DOCA can be made to produce or to aggravate inflammation, but only under very rigid and fixed experimental conditions. What appears closer to the truth is that, in general, each of the corticoids possesses this inflammatory action to a negligible, slight, or great degree, a variation which is characteristic of many of their other physiologic actions. Aldosterone, for example, has little anti-inflammatory action but pronounced salt effects. Most of the recent therapeutic advances have emerged from the synthesis of steroids which possess more anti-inflammatory action and less salt action than cortisone. For example, by introducing a double bond between carbons 1 and 2 in hydrocortisone, a substance called pregnisolon is produced which has ten to twenty times the anti-inflammatory action without alterations in its other effects. The anti-inflammatory action of the corticoids represents but one of their many physiologic actions.

The various corticoids produce *metabolic changes* which influence the behavior of water, salt, carbohydrate, and protein. As already mentioned, the various steroids, in the intact subject, produce these actions in varying degrees. The change in *protein metabolism* has already been discussed in terms of gluconeogenesis; a quality which is possessed to a marked degree by hydrocortisone, little or not at all by DOCA. The influence of the corticoids on *carbohydrate metabolism* is partly due to the release of glucose from tissue protein breakdown. But the effect is probably far greater than this, as first shown experimentally in 1934 by Long and Lukens (6), who showed that adrenalectomy alleviated many of the consequences of pancreatectomy. Cortisone, when given to animals, is diabetogenic, producing both hyperglycemia and glycosuria. This appears to be, at least partially, responsible for the so-called "traumatic diabetes," which has been observed after operation and injury (16) (Fig. 3), and which will be mentioned later. Recently, adrenalectomy has proved beneficial in Kimmelsteil-Wilson's disease, a serious and usually fatal complication of juvenile diabetes.

Water and salt metabolism is greatly influenced by the corticoids which, in a normal subject, will cause retention of water and sodium and an increase in the output of potassium—phenomena that are also normal metabolic effects of injury. The purpose of this reaction is not known, nor is the mechanism clearly understood, although it is probably mediated through changes in renal function. There is a possibility, however, that these changes may be the result of alterations in cell permeability, mentioned above as apparently being one of the mechanisms of the anti-inflammatory action. The salt action is possessed to the greatest degree by the 17-desoxy-CS, especially aldosterone. The group is therefore often called mineral corticoids. The salt action is possessed only slightly by the 17-OHCS which, by contrast, are often referred to as glucocorticoids. Aldosterone has a salt-retaining activity ten times greater than DOCA, and has no influence on carbohydrate metabolism or on the eosinophils, which is discussed below. Aldosterone is also a naturally occurring steroid, having been found in normal blood and urine. It differs chemically from DOCA only in the nature of its carbon 18 position, which has an aldehyde group, CHO instead of CH_3 as in DOCA.

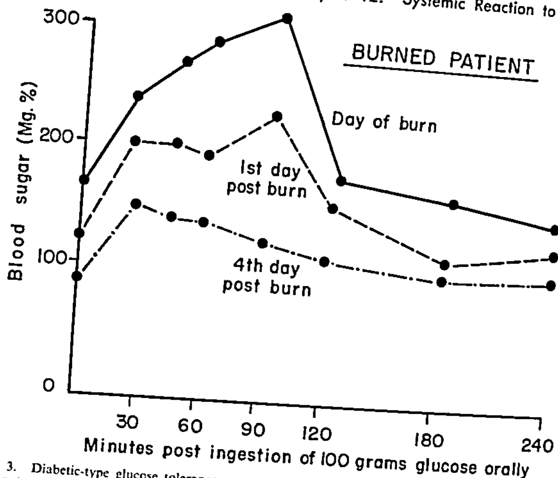

Fig. 3. Diabetic-type glucose tolerance curve following trauma. The hydroxycorticosteroids (Group I) are antagonistic to insulin since they increase the production of glucose (gluconeogenesis). A transient pseudodiabetic curve results.

Hyponatremia, during the post-traumatic and postoperative period, may also be due to the action of the mineral corticoids, although this is not certain. This finding does not appear to be due to water intoxication, as discussed elsewhere, nor to a salt deficiency. This phenomenon of hyponatremia is remarkable because it coincides with the positive sodium balance which follows sodium retention—due presumably to the increased secretion of aldosterone. The evidence of post-traumatic hyponatremia comes from several sources. One of the most convincing is a study of 25 Korean War battle casualties by Howard and his associates (16), 17 of whom showed a drop from the normal concentration of 140 mEq. per liter to levels of 125 mEq. per liter or lower, one as low as 109 mEq. per liter, during the first few days after injury. The plasma potassium was occasionally elevated, especially with the onset of oliguria. In a few instances the rise in potassium and the fall in sodium were strikingly coincidental. Postoperative hyponatremia is especially prone in patients with cardiac and hepatic disease and after valvulotomy for mitral stenosis.

Although there is no immediate explanation of this fall of plasma sodium, one cannot overlook the possibility of a change in cell permeability. The great mass of muscle, and the hepatic, renal, and other cells, with their high intracellular concentration of potassium enclosed in a vast bath of fluid containing largely sodium ions, might readily exchange sodium for potassium. Such an explanation awaits further study, although it has been definitely demonstrated to occur following injury to cardiac muscle. In the meantime, several therapeutic implications can be emphasized. First, it is possible that the administration of sodium chloride in isotonic or hypertonic solution for the correction of unexplained post-traumatic hyponatremia may

lead to more harm than good when the low plasma level is not due to a deficiency. Second, intravenous alcohol (20) and mannitol (21) have been recommended to restore this disturbance in salt metabolism on the basis of evidence which deserves further clinical trial.

The *circulatory changes* under the control of the adrenal cortex are shown by the fact *that shock often follows atrophy or inactivity* of the adrenal cortex. This is an old observation and is apparently associated with the physiologic action of the 17-OHCS rather than the 17-desoxy-CS. The mechanism is poorly understood. One explanation is the possible influence of the corticoids on the vasomotor tone of the arterioles or capillaries. In view of the established action of cortisone on capillary permeability, its action may be due to a conservation of blood volume by halting the loss of fluid through capillaries throughout the body, as mentioned above. Improvement in the peripheral circulation following the intravenous infusion of hydrocortisone has been indicated in certain cases of shock after prolonged operations (22). This finding has not been substantiated in experimental animals in hemorrhagic shock (23). It has been particularly observed in *poor-risk tuberculous patients after pulmonary resection* (24). Shock on sudden withdrawal of cortisone after long-continued therapy therewith, as mentioned below, is presumably due to adrenocortical atrophy and likewise responds to cortisone therapy.

The *lymphoid changes* produced by adrenocortical steroids were first discovered by Dougherty and White (25), who found that adrenocortical stimulation with ACTH was followed by a dissolution of lymphocytes in

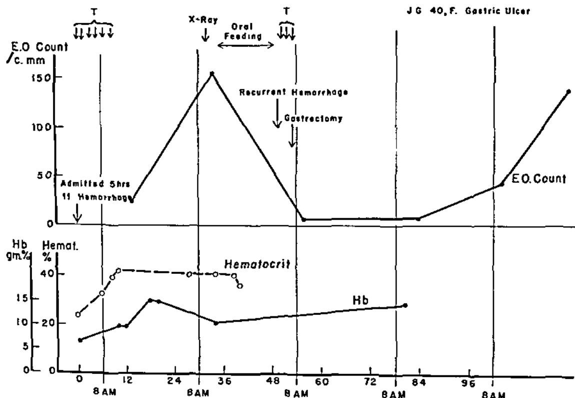

Fig. 4. Recurrent massive gastrointestinal hemorrhage. The patient was a 40-year-old housewife who was in shock when first seen in the receiving room following a massive hematemesis. There was good response to blood transfusion, although it is probable that the amount given (3 liters) was somewhat excessive. A barium meal revealed a gastric ulcer and she was started on oral feeding. The next morning she had a recurrent hematemesis and was promptly taken to the operating room and a gastric resection including the ulcer performed. Recovery and subsequent course were uneventful. Note the response of the eosinophils to each stress. This is normal and also occurs after infusions of ACTH, as shown in Figure 5.

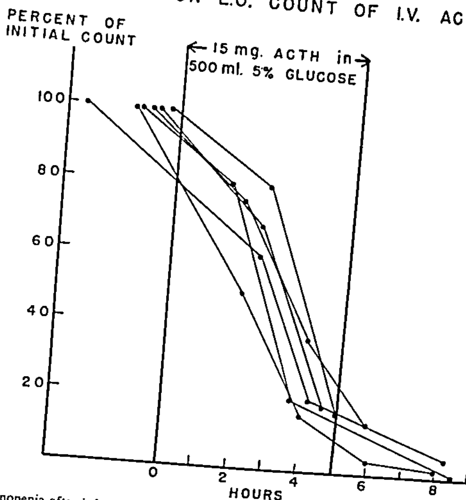

Fig. 5. Eosinopenia after infusion of ACTH. The above curves are from six relatively normal human subjects. Note that it took about eight hours for the eosinophils to disappear, even after a five-hour infusion. This effect is not achieved unless the infusion is continued for at least four hours, regardless of the dose employed. It is likely indeed that the same curves would have been possible with a dose of 5 mg. or less.

the blood and in the lymph nodes. The purpose of this reaction is unknown, but it may be concerned with producing an increase in the resistance of the body to infection inasmuch as this reaction is accompanied by the release of gamma globulin and perhaps other plasma proteins. Dougherty and Noble (26) found a pronounced fall in lymphocyte count in rats following a single trauma, the value returning to normal in 48 hours—an observation soon confirmed clinically. Later it was observed that this phenomenon was shared by the eosinophils (Fig. 4) which, being much easier to count, are now commonly employed to measure pituitary-adrenal response to trauma. Eosinopenia also follows ACTH infusions of more than 4 hours (Fig. 5) and cortisone injections. The historical development of this laboratory test is of considerable interest.

Schilling (27), as early as 1929, pointed out that while trauma and infection provoked an increase in the total leukocyte count (leukocytosis), the increase was solely in the neutrophils, a change called a "shift to the left." But he also found that the eosinophils did not increase and, indeed, tended to diminish or disappear during the acute phase, returning to normal or higher levels upon recovery. Even earlier than this, in 1917, Krumbhaar (28), while experimenting with guinea pigs subjected to various injuries, noted that the eosinophils tended to disappear despite the fact that the total number of white cells rose. Neither of these observers knew of the possible influence and significance of

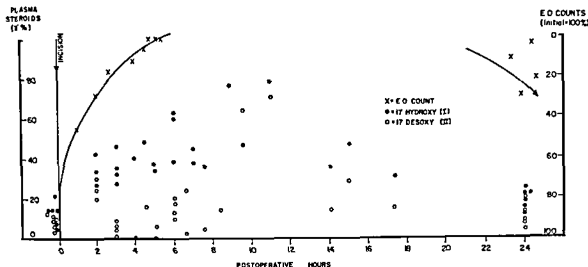

Fig. 6. Effect of operation on eosinophil count and on plasma steroid concentration. The eosinophil count (scale on the right) drops sharply during the first four hours after the beginning of operation. At the end of 24 hours, the cells are beginning to reappear. The concentration of the 17-hydroxycorticosteroids in the plasma increased rapidly during the first few hours. The concentration of the 17-desoxycorticosteroids did not consistently increase; indeed, it fell to zero in several patients.

these findings on the activity of the adrenal cortex. However, changes in the blood picture following the alarm reaction were described in 1939 by Dalton and Selye (29). More recent observations have shown that the eosinophils actually disappear from the peripheral blood not only after operation (Fig. 6) but also following the slow infusion either of ACTH or of cortisone, and even of epinephrine. Steroids of the cortisone group (17-OHCS) are far more active in this respect than the others. Nevertheless, eosinopenia does not always follow trauma, especially when local anesthesia is employed (30).

Other blood changes are known to occur after operation or trauma and may perhaps also be in part due to the primary or secondary effect of corticoids, although the evidence at present is insufficient to draw such a conclusion. These changes, which include anemia and increased blood coagulability, are discussed later in this chapter. Other outlying effects of injury, also described later, may be part of the pituitary-adrenal reaction, although the evidence is still slight.

2. Changes in Adrenocortical Secretion. The evidence is incontrovertible that there is an increased secretion of corticoids following stress as well as following injection of ACTH. This conclusion is based upon results of steroid analyses of adrenal as well as peripheral venous blood and of urine, from both animals and man. Of the many methods of corticoid analysis, the most valuable are based upon meticulous extraction, hydrolysis, column chromatography, and various colorimetric reactions. Confirmatory data have also been obtained by paper chromatography. Biologic methods were the earliest used. These were based upon the amount of hepatic glycogen which was deposited in adrenalectomized animals after the injection of urinary excretion of cortisone or cortisonelike materials, which were capable of inducing gluconeogenesis. These substances have often been called glucocorticoids or cortin. Biologic methods have now been replaced by chemical methods which are, in general, more precise and easier to perform.

In human peripheral blood, the concentration of 17-OHCS is about the same as that of 17-desoxy-CS or about 10 μg. per cent. Analysis of individual steroids shows that Compounds B and F represent the two groups respectively and that the former is present in half the concentration of the latter. Analysis of blood from the adrenal vein usually shows a greater difference between F and B, in favor

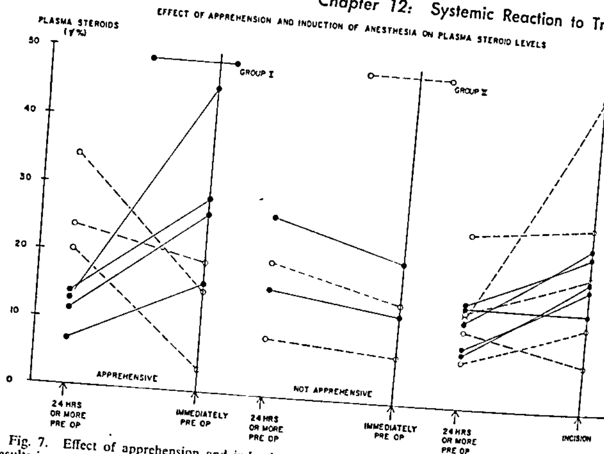

Fig. 7. Effect of apprehension and induction of anesthesia on plasma steroid levels. Apprehension results in a marked rise in the plasma concentration of 17-hydroxycorticosteroids (Group I) but not of the 17-desoxycorticosteroids (Group II). Induction of anesthesia had an additive effect, resulting in a rise in the concentration of both fractions.

of the former. Unfortunately, samples of adrenalvenous blood are often admixed with vena caval and renal blood. Moreover, the specimens usually are from patients suffering terminal mammary cancer, and thus may not be representative of that in the normal person. It is generally agreed, however, that, in man, Compound F or hydrocortisone is the main representative of the 17-OHCS in the peripheral blood.

Increases of corticoid in the peripheral blood following operation were first noted by Nelson and Samuels (31), who measured the 17-OHCS by a modified Porter-Silber reaction during 6 to 10 postoperative hours. Postoperative studies for longer periods, up to 72 hours, were made by Elman and his coworkers (32), the data for the first 24 hours being shown in Figure 6. These observations are of special interest also because they include determinations of the 17-desoxy-CS which did not share in the increase shown by 17-OHCS, but actually fell to zero in some cases. As already mentioned above, there is other evidence that 17-desoxy-CS groups of corticoids were not under pituitary control (Fig. 7). No differences were noted in relation to age or sex, but the less severe operations were followed by only slight or no elevation in the blood level of 17-OHCS.

As far as urine studies are concerned, mention should first be made of the tremendous literature on the determination of the 17-ketosteroids. It is now known that this group, as measured by the Zimmerman reaction (33), contains only 19 carbon atom steroids and really represents a sort of wastebasket containing not only metabolites of the corticoids but also such other steroids as progesterone and testosterone. Moreover, there is so much confusion as to the significance of these measurements as a measure of adrenocortical activity that no attempt will be made to summarize these data. In general, the 17-ketosteroid studies have shown little or conflicting changes after operation, as illus-

TABLE 2. The Effect of Gastrectomy on Urinary Steroid Excretion (mg. per 24 hours)

	Preoperative Days		Postoperative Days				
	−2	−1	1	2	3	4	5
17-Ketosteroids							
Patient 1	11.0	7.0	18.0	12.0	—	12.0	10.0
Patient 2	14.0	10.0	11.0	9.0	13.0	5.0	—
17-Hydroxycorticosteroids*							
Patient 1	4.4	3.7	29.0	11.8	—	4.3	3.2
Patient 2	2.4	3.4	28.7	10.6	4.4	3.3	—

* In five normal subjects, the 24-hour excretion rose during the day of a four-hour intravenous infusion of ACTH (25 mg.) from 2.8 to 8.2, from 3.7 to 16.0, from 2.5 to 28.0, from 2.7 to 6.7, and from 9.0 to 12.0 mg.

trated in Table 2. Many of the unexplained variations are due to differences in the method of hydrolysis. Extracts of urine must usually be hydrolyzed because the urine contains very few free steroids, most of them being present as glucuronic acid or sulfuric acid conjugates. Thus, analysis of total corticoids depends upon adequate and careful hydrolysis. When mineral acids are used instead of glucuronidase, some loss of steroids occurs. On the other hand, a few of the reports contain data based upon analysis of nonhydrolyzed extracts, thus representing free steroids which, of course, would give much lower figures.

Measurement of 21 carbon corticoids in the urine may be expected to give more exact information regarding changes in adrenocorticoid activity, particularly when the Porter-Silber color reaction is used. Because of the greater specificity, this reaction is being used more and more, even though it measures only the 17-OHCS. Comparison of data from different sources may still present difficulties due to the influence of varying methods of hydrolysis, as mentioned above. In many studies, moreover, the so-called formaldehydogenic method which is relatively nonspecific, is used, even though it is supposed to measure both 17-OHCS as well as 17-desoxy-CS. In the following summary an attempt will be made to include significant data on the urinary corticoid excretion both in the normal and after stress.

In normal individuals, Venning and Browne (34), using a biologic method, found that male subjects excrete twice as much cortin as females, an observation which was recently confirmed by Reddy, Jenkins, and Thorn (35), who used the Porter-Silber method. As to age, McFarlane and associates (36), using the same method, found no difference in the normal excretion of urinary corticoids at different ages. Following an intravenous infusion of ACTH, however, these observers noted a greater increase in urinary output in the young than in older subjects. By contrast, Dobriner (37), using even more careful biochemical methods, found that individual variations followed the intravenous infusion of ACTH in old and young subjects, but not in relationship to their age.

Following operation or injury, there is general agreement on an increased urinary excretion of corticoids, although variations in degree are fairly wide. For example, Venning and Browne found as much as ten times the normal excretion of cortin in the urine of three severely burned patients, an increment which persisted for three weeks before returning to the base level. Elman and his co-workers obtained similar, but less pronounced, findings using a refined method of hydrolysis and the Porter-Silber reaction. In females after hysterectomy, the rise was much less pronounced. In the extensive studies carried out during the Korean conflict (16, 38), using a modified formaldehydogenic method, the urinary excretion often rose to five to fifteen times the normal on the first or second post-traumatic day.

3. Metabolic Changes in Adrenocorticoids. From a variety of studies, including analyses of adrenal venous blood, peripheral

blood, and urine, it is now known that a number of changes occur in the free, biologically active, adrenal cortical steroids after they leave the adrenal vein and are carried to the various tissues of the body. *Many of these* changes are known, others still unknown. Their importance has already been suggested by the observations made in adrenalectomized patients.

Conjugation of the steroids with glucuronic acid and, undoubtedly, with one or more of the organic acids of the body is perhaps one of the best known. This change probably occurs in the liver and renders the steroid biologically inactive. This phenomenon probably explains the early clinical observation that arthritis improved whenever a patient developed jaundice, presumably because more free steroids remained in the peripheral blood. Conjugation and reduction, with or without conjugation, may occur in other tissues, perhaps even in malignant tissue. Conversely, some of these steroids may have an influence on the behavior of malignant cells. The fact that the clinical regression of tumor has been observed in some patients with extensive breast and prostatic cancer following adrenalectomy and hypophysectomy suggests such a relationship.

Changes other than conjugation and reduction may occur which also render some of the free steroids inactive. Reduction may occur without conjugation at the 31 position from keto- to hydroxy- with saturation of the 4Δ double bond as well. Other conversions are possible and a few probable. A change from DOCA to pregnanediol has apparently been demonstrated both in animals and in man. Other changes even from the 17-OHCS to 17-desoxy-CS may occur, although definite proof is lacking.

The *renal clearance of adrenal corticoids* is also of importance in their peripheral behavior and therefore in evaluating the pituitary adrenal reaction. Thus the excretion rate for the various steroids, when increased or decreased, will play an obvious part in their blood levels and thus on the degree of their physiologic actions. An analogy may be drawn with the effectiveness of such drugs as chemotherapeutic agents normally excreted in the urine. The blood levels of penicillin, for example, are always higher in anuria.

THERAPY IN THE ALARM REACTION

Once ACTH and cortisone became available as active agents, it was natural that attempts would be made to extend their therapeutic application to surgical patients. At first it was believed that giving ACTH after operation or injury would aid nature's response; the argument being that, since the pituitary-adrenal reaction is a normal mechanism, making it more intense might increase its effectiveness. It soon became apparent that the matter was not quite so simple, and more knowledge was necessary. One might say, in general, that therapy in regard to the alarm reaction might take one of two directions. 1. An attempt might be made to decrease the intensity of the response should it become excessive; 2. It must be determined whether there is a need for supplying missing hormones when the normal response is absent or inadequate. Such an approach obviously must take into account the wide variations in *the spontaneous reaction to trauma. In the* following discussion, therefore, three types of response to trauma will be described, based largely on clinical considerations. In some instances there seems to be a good correlation with these clinical changes and differences in the pituitary-adrenal reaction.

In Group I are included young, healthy, well-nourished males, in whom severe injury is usually followed by extreme prostration, moderate fever, and huge losses of tissue protein; changes which undoubtedly mean an intense adrenocortical response. The question may be raised: Would a less intense response be clinically desirable? A positive answer is suggested by the following experience, during the Korean conflict. A soldier, who suffered extensive injury and required radical surgical procedures, showed only a moderate systemic reaction, little hepatic insufficiency, and remarkably good postoperative healing. Study of the urinary output of corticoid showed scarcely any increase, indicating a rather moderate pituitary-adrenal reaction. This correlation of a favorable clinical response to trauma with a modest pituitary-adrenal reaction is also supported by the fact that females in whom the alarm reaction is less severe than in males (see above), react much more violently and indeed recover more rapidly after

operation or injury than the male, other things being equal. One might speculate regarding this difference by postulating that the male, having been through the centuries more subject to accidental trauma, has developed a more intense pituitary-adrenal response than the female. In any case, should it prove true that a less intense pituitary-adrenal reaction would be clinically desirable, attempts to lower the intensity of the response in healthy males would seem justified, at least within certain limits and by means still unknown.

Group II comprises well-nourished patients of advanced years, and females in general. It is an old clinical observation that older patients, somewhat as females, react less violently and seem less prostrated than younger individuals, even after severe operation. While it is true that such older patients are unable to withstand infection, shock, and other complications as well as more youthful individuals, their postoperative convalescence in the absence of complications is often much smoother than that of younger individuals. Should this desirable objective be a manifestation of a less intense pituitary reaction, it would add to the indications mentioned above for therapeutic means of reducing the intensity of the alarm reaction in young male adults. The idea of using a preliminary infusion of ACTH several days before an elective operation, to achieve such an objective, has been advanced (39), but lacks proof.

Group III comprises patients in poor general condition, who are poor risks for any significant trauma. The question arises, Is this unfavorable response to trauma related to impaired or absent pituitary-adrenal reaction? It is, of course, well known that in Addison's disease any harmful stimulus threatens life. This is also true of patients in whom adrenal atrophy follows the withdrawal of cortisone after prolonged therapy therewith. Cachexia is also known to be associated with a decrease in pituitary function and thus with a suppression of ovarian, testicular, and adrenocortical activity. Underactivity of the adrenal may also occasionally occur in postoperative patients who go into unexplained shock, a state which responds dramatically to cortisone or hydrocortisone (22). The favorable response of patients severely ill with thyroiditis and hepatitis to cortisone therapy may also be due to a similar need for this steroid, although the anti-inflammatory effect of cortisone may be the explanation. In any case, further observations will be necessary to determine which is the cause. The eosinophil count is an easy test and should perhaps be used more often despite its pitfalls. For example, a drop to zero after operation, followed by a rise within 24 to 48 hours is normal, whereas failure to remain at zero or failure to fall again in the face of severe complications might in itself indicate sudden adrenocortical impairment and the therapeutic need for adrenocortical steroids. The main pitfall in the interpretation of the eosinophil count is its failure to fall, particularly when spinal anesthesia is used. In any case, the indications for supplying steroids or ACTH would seem direct and logical in this group of patients. What is needed, of course, is a better clinical method of determining the inadequacy or failure of the alarm reaction.

In *summary*, one may say that the therapeutic application of knowledge of the alarm reaction to surgical patients awaits further information. Although it is obvious that the integrity of the pituitary and adrenal glands is essential for survival, and that an adequate response by these glands is probably also necessary for the body's successful resistance to harmful stimuli, this does not mean that the most intense response is necesarily the most beneficial to the patient. An excessive alarm reaction may, in fact, be detrimental and offers a therapeutic challenge for the future. More significant clinically and therapeutically, at the present time at least, are the many situations, some definite, others indefinite, when adrenocortical function is impaired or even absent, situations in which the use of ACTH and cortisone may be of direct clinical benefit.

Cortisone Therapy and Surgical Disease. The prolonged use of cortisone by patients with a variety of such chronic diseases as arthritis and asthma has a practical surgical aspect whenever these patients become subject to a surgical disease requiring either an elective operation, as cholecytitis, or an emergency operation, as acute appendicitis. In the latter case, it has been found that the steroids (like antibiotics) so greatly reduce the usual signs of peritoneal irritation that the diagnosis

blood, and urine, it is now known that a number of changes occur in the free, biologically active, adrenal cortical steroids after they leave the adrenal vein and are carried to the various tissues of the body. Many of these changes are known, others still unknown. Their importance has already been suggested by the observations made in *adrenalectomized* patients.

Conjugation of the *steroids* with glucuronic acid and, undoubtedly, with one or more of the organic acids of the body is perhaps one of the best known. This change probably occurs in the liver and renders the steroid biologically inactive. This phenomenon probably explains the early clinical observation that arthritis improved whenever a patient developed jaundice, presumably because more free steroids remained in the peripheral blood. Conjugation and reduction, with or without conjugation, may occur in other tissues, perhaps even in malignant tissue. Conversely, some of these steroids may have an influence on the behavior of malignant cells. The fact that the clinical regression of tumor has been observed in some patients with extensive breast and prostatic cancer following adrenalectomy and hypophysectomy suggests such a relationship.

Changes other than conjugation and reduction may occur which also render some of the free steroids inactive. Reduction may occur *without conjugation at the 31 position* from keto- to hydroxy- with saturation of the 4Δ double bond as well. Other conversions are possible and a few probable. A change from DOCA to pregnanediol has apparently been demonstrated both in animals and in man. Other changes even from the 17-OHCS to 17-desoxy-CS may occur, although definite proof is lacking.

The renal clearance of adrenal corticoids is also of importance in their peripheral behavior and therefore in evaluating the pituitary adrenal reaction. Thus the excretion rate for the various steroids, when increased or decreased, will play an obvious part in their blood levels and thus on the degree of their physiologic actions. An analogy may be drawn with the effectiveness of such drugs as chemotherapeutic agents *normally excreted* in the urine. The blood levels of penicillin, for example, are always *higher* in anuria.

THERAPY IN THE ALARM REACTION

Once ACTH and cortisone became available as active agents, it was natural that attempts would be made to extend their therapeutic application to surgical patients. At first it was believed that giving ACTH after operation or injury would aid nature's response; the argument being that, since the pituitary-adrenal reaction is a normal mechanism, making it more intense might increase its effectiveness. It soon became apparent that the matter was not quite so simple, and more knowledge was necessary. One might say, in general, that therapy in regard to the alarm reaction might take one of two directions. 1. An attempt might be made to decrease the intensity of the response should it become excessive; 2. It must be determined whether there is a need for supplying missing hormones when the normal response is absent or inadequate. Such an approach obviously must take into account the wide variations in the spontaneous reaction to trauma. In the following discussion, therefore, three types of *response to trauma* will be described, based largely on clinical considerations. In some instances there seems to be a good correlation with these clinical changes and differences in the pituitary-adrenal reaction.

In Group I are included *young, healthy, well-nourished males, in whom severe injury is usually followed by extreme prostration, moderate fever, and huge losses of tissue protein;* changes which *undoubtedly mean an intense adrenocortical response.* The question *may be raised: Would a less intense response be clinically desirable? A positive answer is suggested by the following experience, during the Korean conflict. A soldier, who suffered extensive injury and required radical surgical procedures, showed only a moderate systemic reaction, little hepatic insufficiency, and remarkably good postoperative healing. Study of the urinary output of corticoid showed scarcely any increase, indicating a rather moderate pituitary-adrenal reaction.* This *correlation of a favorable clinical response to trauma with a modest pituitary-adrenal reaction is also supported by the fact that females in whom the alarm reaction is less severe than in males (see above), react much more violently and indeed recover more rapidly after*

sions, may also occur. From an extensive study of the war-wounded by Beecher (41), he concluded that the sensorium was influenced not so much by pain as by apprehension, fear of physical disability, concern as to the outcome of the injury, and other emotions. In a few instances, the emotional factors are favorable, in terms of relief resulting from being detached suddenly from danger, or unfavorable, in terms of the deaths of comrades by their sides or extensive injuries occurring next to them. In civilian injuries, some of these emotional factors also play a part though to a lesser extent. They are all part of the psychogenic factors of surgical diseases already mentioned, and discussed in detail elsewhere (43).

Sensorial changes may also be due to specific causes—for example, anoxia—which may follow peripheral circulatory impairment (shock), loss of blood, and so forth. Restlessness, such abnormal behavior as picking at the bed clothes, or frank apathy may occur. Occasionally, the patient in shock may be deeply obtunded although rarely is he comatose. Unconsciousness from shock usually means complete cessation of cerebral blood flow, consequently cardiac arrest and, of course, is incompatible with life for longer than four minutes. Infection, if severe, also produces a variety of sensorial disturbances which, when severe, are called "toxic psychosis." Renal impairment is also followed by mental changes well known in cases of uremia. Electrolyte disturbances which lead to changes in mental behavior have already been discussed.

Aside from the cerebrum itself, the peripheral nerves may also play a part in some of the nonspecific effects of trauma by initiating reflex changes such as vasospasm in peripheral arteries and even in the renal arteries. Much has been written of these peripheral effects and of the value of nerve block or even of sympathectomy in therapy.

2. The *liver* is frequently influenced by trauma beyond its anatomic boundaries. This is manifested by impaired function, rarely severe enough to produce jaundice (not due to increased hemolysis or biliary obstruction). Impaired hepatic function, if severe enough, is, of course, a threat to life itself insofar as the liver is an essential organ. Even moderate degrees of hepatic insufficiency are harmful by decreasing the resistance of the body to disease and injury. One of the functions of the liver deals with the peripheral metabolism of adrenocortical steroids and may, of itself, have a decisive influence, although little is known thereof at present. However, impaired hepatic function has been shown to lead to a decreased rate of steroid conjugation and thus to the accumulation of a larger amount of free steroids in the peripheral blood. Whether this is favorable or unfavorable to the body's defense against injury remains unknown. It is curious that, despite this mechanism, cortisone therapy has been reported as beneficial in hepatitis.

The evidence of hepatic impairment after injury is unquestioned but not extensive. Tagnon and associates (44) found abnormal bromsulphalein retention in 14 of 20 patients after operation. Keeton, Cole, and associates (45), using urobilinuria as their test, found hepatic impairment after inhalation but not after spinal anesthesia. The impaired function reached its maximum by the third postoperative day and was made worse by infection. During the Korean War, Scott, Olney, and Howard (46), found increases in the plasma total and indirect bilirubin immediately after injury, reaching a peak five times the normal six hours afterwards. The urine urobilinogen rose simultaneously in a few of the cases studied. Since the urobilinogen is normally manufactured from bilirubin excreted in the bile, it is not surprising that Galt and Hunter (47) found that an intestinal antiseptic (aureomycin) led to the appearance of bile and the disappearance of urobilinogen in the stool. It is therefore clear that urobilinogen measurements are probably of little or no significance as a measure of hepatic function in patients in whom such antibiotics have been used. The bromsulphalein retention in the above battle casualties was usually elevated on the first postoperative day and was most marked (as high as 42 per cent) in those in severe shock, especially those with abdominal wounds. Thymol turbidity remained unchanged, while cephalin flocculation was increased after injury. Plasma prothrombin activity was somewhat depressed following injury and transfusion of stored blood. The synthesis of fibrinogen was apparently unim-

may be completely missed. It has become clear, therefore, that acute appendicitis, perforated peptic ulcer, or similar surgical emergencies, in patients receiving these steroids, represent a real hazard. In such cases, it is important, of course, that the intake of these steroids be maintained should operation be carried out. This is equally true of elective operations, although here it may be more advisable to combat adrenal atrophy by gradual withdrawal of the drug and to operate later, when adrenocortical function has been restored to normal. This use of cortisone in infections has been discussed elsewhere.

A number of monographs are available dealing with the effects of stress on changes in the pituitary and adrenal function. A large, complete, and recent review is the report by Selye (39). The monographs by Hasner (40) and a recent brief summary by Zimmerman (33) are also suggested for further reading.

THE INFLUENCE OF THE WOUND

Certain systemic effects of trauma are due directly to the wound itself, most of them producing well-known reactions; for example, loss of blood leading to shock needs no further comment here and is discussed in detail in Chapter 13. The role of the wound as a portal of entry for systemic infection is also discussed elsewhere. The local pain, the degree of which is often greatly exaggerated, as shown in a study of war wounds by Beecher (41), does, nevertheless, act as a stimulus to the pituitary-adrenal or stress reaction, as already discussed. Of some historical interest is the "noci-association" theory of Crile (42) promulgated over forty years ago. Believing that harmful pain stimuli from the wound exerted remote deleterious effect, even in the deeply anesthetized patient, he blocked the area of the incision with novocain as a routine. Although this procedure is now seldom if ever used, the basic principle of gently handling tissue, as taught by Halsted and others, undoubtedly minimizes many of the harmful systemic effects of injury. The patient under general anesthesia may not react overtly at the time, but clinical experience has shown that rough surgery is much more likely to lead to a rough convalescence. This may, in fact, be due to the increased sensory stimulation thus evoked, but is probably due just as much or more to the increased tissue damage inflicted.

The extent of tissue damage is not only significant in relation to blood loss and the liability of infection but also in altering cell permeability in the entire wound area, especially when it is extensive and involves much muscle tissue. A great deal is being learned of this mechanism, particularly as it applies to the sodium, calcium, potassium, and perhaps magnesium ions. Interchanges between the former two, which are extracellular, and the latter two, which are intracellular, may prove of great clinical importance, especially in terms of replacement therapy with properly balanced electrolyte solutions. Suggestive of such changes in cell permeability are the investigations of Howard and associates (16) during the Korean War, showing that extensive injury is often followed by a fall in plasma sodium and sometimes by an increase in plasma potassium. Another factor in the wound capable of producing such systemic effects as fever and other "toxic" symptoms, is the release of toxic substances from the breakdown of large amounts of hemoglobin.

THE OUTLYING EFFECTS

In this section are discussed the systemic nonspecific effects of trauma not directly involving, but greatly influencing, the central nervous system, the liver, kidneys, and gastrointestinal tract. Respiratory and cardiac changes are even more important than those in other systems, but are discussed elsewhere.

These remote consequences of injury may be due to circulatory changes, to reflex nerve mechanisms, to the effects of increased adrenocortical steroids, or to other mechanisms. In any case, the changes may be so severe as to lead to actual tissue damage and even to death. Knowledge of these reactions therefore must be possessed by all physicians or surgeons dealing with the injured patients. Indeed, many of these outlying effects are shared by nonsurgical diseases in which severe stress is involved.

1. The injured patient exhibits perhaps the most obvious changes in the *central nervous system* function when he becomes depressed or loses consciousness or goes into coma. Hyperactivity as shown by apprehension, restlessness, or even delirium and convul-

crease in salivary secretion was also observed. Most striking was an experiment in which there was almost complete inhibition of salivary secretion in a blood donor after the bleeding of 500 ml. A controlled flow of 5 ml. per minute fell to less than 1 ml. almost immediately and returned only gradually to normal five hours afterward. A time factor probably explains the conflicting observations of increased uropepsin excretion after trauma and after ACTH stimulation (50). This probably also explains the observation that perforative peptic ulcer may occur during the postoperative period, presumably as a stress phenomenon (51). In the early days of cortisone therapy, it was found that, when used in patients with peptic ulcer, perforation often followed. It is now well known that the peak of adrenocortical stimulation by operation is not reached before eight hours (38). Thus the findings of achlorhydria by Howard may have been due to an immediate epinephrine response rather than to the effects of increased adrenocortical activity. It should be recalled that inhibition of gastric function was observed by Cannon in his early studies on fear, rage, and pain, and is, of course, a common clinical observation after various types of stress. A study was made of gallbladder function in the Korean conflict (52). Ten injured soldiers were studied by means of cholecystography and a temporary nonvisualization was established. This certainly must be added to the list of the nonspecific effects of trauma as one of the outlying manifestations in systems far removed from the wound.

OTHER CHANGES AFTER INJURY

Among the many observations made during injury, several have not been mentioned and are here presented. A fall in serum iron has been noted after operation (53), as well as a drop in the level of plasma amino acids (54, 55) associated with a fall in blood lipids. Similar falls in blood amino acid levels have been noted following infusion of ACTH.

The oliguria, the salt retention, and the potassium loss after operation and by the administration of adrenocortical steroids have already been noted. Calcium is also lost after trauma, especially following fractures, but this may be due more to the *atrophy of disuse* than to a systemic effect of injury itself. Atrophy always plays a potential part in any operation, injury, or even medical disease that is bed-confining. Moreover, muscle as well as bone is affected and accounts for much of the protein wastage following disease, entirely apart from that due to gluconeogenesis. The effects of such disuse atrophy have been studied in detail (56).

The vitamins are probably involved in the systemic effects of injury, but most is known of vitamin C, which disappears rapidly from the blood after injury despite a large intake (57). Since it does not appear in the urine, it is presumed to be destroyed or to have escaped in the damaged tissue. Of interest is the high vitamin C content of the adrenal cortex which, in animals, disappears after stress but does not if the hypophysis is first removed.

The effect of injury on carbohydrate metabolism is well known (58). Gluconeogenesis is probably under adrenocortical control. Hyperglycemia, glycosuria, and ketonuria have all been observed after trauma, but the latter is probably due almost entirely to starvation. A definite impairment in carbohydrate utilization has long been referred to as "traumatic diabetes," first studied in detail by Thomsen (58) in 1938, and later by Taylor and his associates (59).

A trypsin inhibitor in the urine was found by Dillard (60) to increase sixtyfold following a partial gastrectomy, returning to normal by the fifth day; to a fifteen-fold increase following a jejunostomy. The complicated changes in blood coagulation after operation are too confusing to discuss here, but the latest observations deal with an increase in a trypsinlike protease called plasmin (61), which is somehow related to the fibrinolytic ferment that produces liquefaction of cadaver blood and perhaps to unusual postoperative bleeding.

Post-traumatic Blood Changes. A fall in hemoglobin as well as in plasma protein concentration following operation and injury has often been noted and usually attributed to losses in the damaged tissues by actual bleeding or by inflammation (extravasation). Undoubtedly, much of it is to be explained in this way. Mention should be made, however, of another mechanism which may be at least partially responsible for the anemia following

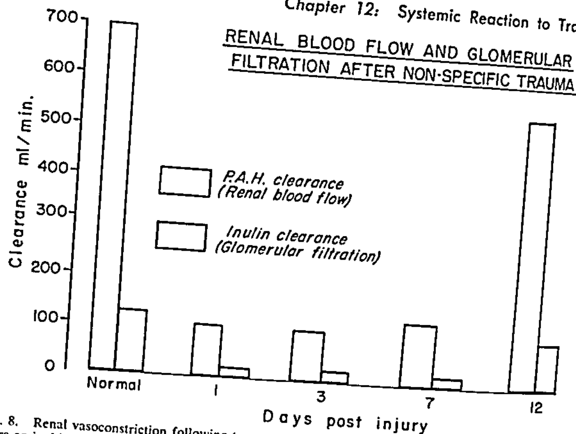

Fig. 8. Renal vasoconstriction following trauma. As a result of renal vasoconstriction, the clearances of para-aminohippurate and inulin, measuring renal blood flow and glomerular filtration respectively, decrease sharply after severe trauma. This response may persist for several days after restoration of a normal blood volume. This decreased renal function, at a time when the nitrogen load for excretion is maximal, may result in an elevated blood urea nitrogren concentration during the postoperative or post-injury period.

paired (46), the concentration increasing.

3. *Renal impairment* is so frequent after injury that it must perhaps be considered the most serious of the outlying effects of trauma. The causes are many. Post-transfusion reactions are well known. Shock and hypotension, by reducing renal blood flow, are often important factors (Fig. 8). After the central nervous system, renal tissue is perhaps the most sensitive to impairment or failure of blood flow. The time interval is not known exactly, but it is probable that a few hours, certainly less than four hours of complete renal ischemia, will lead to irreversible renal failure. Loss of renal blood flow for such a period may coexist with adequate cerebral blood flow due to selective vasoconstriction, by which a reduced amount of blood may be used to service the kidney at the expense of other tissues. Presumably, regional renal vasoconstriction may also occur, in the absence of blood loss, through reflex arcs initiated by severe pain. The practical significance of vasoconstriction is suggested by observations (48) in which such vasodilating and pain-relieving drugs as papaverine seemed to be followed by improved renal function. Other studies indicate that the autonomic blocking agents do not reverse the vasoconstriction in the renal circulation, suggesting that this response is not mediated by the epinephrine-sympathetic nervous mechanism. This may prove, biologically, to represent a separate response mechanism. The details of therapy in postoperative and post-traumatic renal impairment are discussed elsewhere.

4. The *gastrointestinal tract* is obviously affected by trauma far removed from the abdomen, as shown by the frequency with which the injured, and especially fracture patients, suffer nausea, vomiting, and occasionally paralytic ileus. Specific studies of gastrointestinal function carried out during the Korean War have thrown much light on this phenomenon. For example, it was found by Howard (49) that 10 injured soldiers studied 18 hours after injury showed evidence of decreased gastric secretion and motility. A de-

trauma. The evidence, much of it originally based on both clinical and experimental observations, has been assembled by a young Swedish surgeon, Lars-Erik Gelin (62). Most of the clinical data consist of observations on fracture cases in which, of course, injury is not complicated by anesthesia or by operation. The concentration of hemoglobin in grams in 32 femoral-shaft fractures fell from 8.3 gm. per cent ± 2.3 gm. per cent to 6.2 gm. per cent ± 2.3 gm. by the tenth posttraumatic day, returning gradually to normal. The red cell count paralleled the hemoglobin concentration and the red cell sedimentation rate was in reverse, giving indeed a mirror image of the hemoglobin changes. The color index was unchanged. From a variety of clinical and convincing experimental evidence, this anemia was shown to be largely hemolytic and associated with erythrostasis, a term used to describe the increased viscosity and sludging of the blood, so graphically described in this country a few years ago by Knisely (63). Of considerable theoretical interest was the observation by Galin that low molecular dextran exerted a beneficial effect in decreasing sludging and anemia in contrast to high molecular dextran, which had the opposite influence. These provocative studies should be pursued.

In this country, Cockrell and Naumann (64) have found true hemoglobinemia (not due to artifact) after many operations and injuries and in certain systemic diseases, presumably as a manifestation of hemolysis. Postoperative increases of bilirubin have been frequent, although in most instances they have been explained by changes in hepatic function as well as by the breakdown of extrasavated red blood cells. It is possible, however, that many of these changes may be due to the mechanism described by Galin.

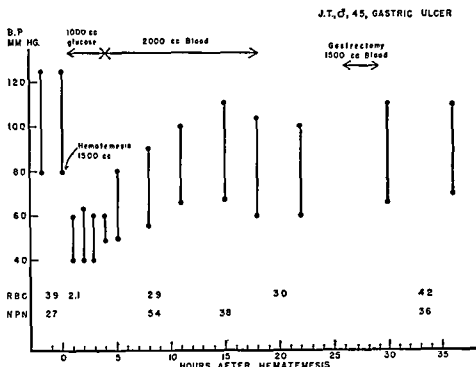

Fig. 1. Shock due to massive gastrointestinal hemorrhage. The patient, in excellent general condition, was admitted for the treatment of a known gastric ulcer. Shortly after admission, he suddenly vomited 1,500 ml. of almost pure blood and later had a tarry stool. Because 1,500 ml. of blood failed to restore his red cell count and because he showed other signs of continuing hemorrhage, he was operated on 24 hours later and an actively bleeding gastric ulcer was found and removed as part of a gastric resection. The postoperative course was uneventful.

Note the prompt fall in the red cell count, showing that hemodilution can occur within 30 minutes of a hemorrhage. Note also the failure of glucose to restore hypotension while blood transfusion was being prepared. It would have been better to give saline, still better to use Dextran. Note also the azotemia (rise of NPN) due undoubtedly to the absorption of digested blood which must have passed in large amounts into the small intestine.

This case is an example of the need for both adequate blood replacement and operation to stop the source of blood loss. (From Elman, R. Surgical Care, Appleton-Century-Crofts.)

From the historic point of view, the terms *primary* shock and *secondary* shock have sometimes been used, but actually they are more a source of confusion than clarification. The first usually refers to shock which occurs immediately after injury, but is transient and rapidly disappears; the second usually refers to shock which appears after an hour or two and is based upon definite and continuing disease, injury, or loss of blood. If these terms were used, secondary shock would really represent in general the type of shock herein considered.

CLINICAL CAUSES OF SHOCK

Of the many clinical recognizable disturbances which may produce shock, it is possible to classify them tentatively into three general categories, as listed below, although in a particular case there may be considerable overlapping. A fourth group is added because of the apparently growing frequency and recognition of adrenocortical insufficiency.

1. **Severe Loss of Extracellular Fluid.** The blood bed is, of course, the most important extracellular fluid compartment; therefore, loss of blood or *hemorrhage* is the most common and serious clinical disturbance which may lead to peripheral circulatory impairment (Fig. 1). The amount of blood lost without other factors that may produce shock varies with the age and sex of the individual and the rate of loss. Ordinarily, shock will follow a single, sudden loss of blood equal to 2 or 3 per cent of the body weight which, in a normal lean adult, is about 1.5 to 2.5 liters.

13

SHOCK AND HEMORRHAGE

Shock and hemorrhage have, by tradition, been discussed together largely because they were supposed to represent similar but different clinical entities, each of which could be differentiated diagnostically. While it is true that hemorrhage alone, without complicating causes, produces more definite and more easily explained and recognized disturbances, it shares with shock the propensity for leading to *peripheral circulatory impairment*, which may be defined as a diminution in the rate of peripheral blood flow. This reduction in the supply of blood to peripheral tissues is the common denominator in all cases of shock, regardless of the contributing or precipitating factors and clinical effects produced. The modern concept is to consider shock as a general term and hemorrhage as one of its most common causes; but there are many other causes, some readily detectable, others difficult to determine and to understand. In many cases, shock is due to more than one cause. Finally, shock itself may produce such secondary manifestations as cerebral anoxia or renal impairment, which may be severe enough to threaten life. To illustrate its complexity, one needs only to realize that shock may follow severe trauma with or without hemorrhage, extensive burns, intestinal strangulation, adrenal insufficiency, cardiac failure, severe cerebral injury, tranfusion reaction, anaphylaxis, insulin-produced hypoglycemia, electrolyte disturbances, and fulminating infections. The term *surgical shock* is usually applied to shock that follows trauma or operation, or to shock which may require operation for its correction. This limitation, however, is often arbitrary. For example, myocardial infarction or a sudden hemorrhage from peptic ulcer may lead to shock. Neither is due to trauma; but the former is of medical, the latter of both medical and surgical interest.

Definition. Although the reader will find a variety of definitions of shock by different authorities (1, 2), its common characteristic, as mentioned above, is peripheral circulatory impairment or failure. Shock may be defined, therefore, as "a clinical state in which there is significant reduction in the peripheral circulation or rate of peripheral blood flow." This definition indicates that there are varying degrees of shock, a fact which is, indeed, in accord with clinical experience. The term is also used, really misused, in other conditions, called "nervous shock," which may occur after hearing tragic news, seeing anything intensely disagreeable or frightening, or experiencing profound fear and excruciating pain. Although sensorial depression may be so profound as to be followed by unconsciousness, as in fainting or syncope, the circulation is usually only temporarily impaired and recovery is prompt. Sometimes confused with shock are conditions producing collapse or prostration in which the circulation is not impaired at all. These are discussed in detail in Chapter 19.

In the following discussion, the subject of surgical shock will be approached from the clinical point of view by describing: (*a*) the various clinical causes, (*b*) the many contributing factors, (*c*) the clinical manifestations, (*d*) the pathogenesis, and (*e*) the treatment. An additional section will be devoted to a discussion of the "crush syndrome."

precipitates shock without other factors. More often these disturbances act as contributing causes, as listed below. Nevertheless, they all greatly influence the degree of shock, as noted especially during observations of the wounded during World War II. In these disturbances, as in the "toxic" effects mentioned above, vasomotor paralysis is probably the important factor in causing shock.

4. **Adrenal Insufficiency.** The occurrence of shock in patients with Addison's disease is, of course, an old observation. In view of recent and increasing use of cortisone, which may lead to adrenocortical atrophy, more patients may be expected to show shock whenever the drug is withdrawn suddenly. Bilateral adrenalectomy is also being carried out increasingly for various diseases, and thus has increased the likelihood of shock due to this cause. Postoperative and post-traumatic shock not explainable by any other clinical cause, as already mentioned, may also be due to transient adrenocortical insufficiency or exhaustion. The mechanism is obscure but may be due to increased capillary permeability and loss of plasma or to an increase in the blood bed because of vasomotor paralysis, as mentioned above.

CONTRIBUTING CLINICAL FACTORS IN SHOCK

The following list of other clinical factors in shock have long been known. Not only do they increase the likelihood and the severity of shock, but they may be able to initiate it themselves in isolated instances. The dividing line between these factors and those listed above is sometimes narrow or they may develop, but recognition of them separately is important, particularly since they play such an important part in therapy, as discussed later.

1. *Exposure to cold* may be a primary cause of shock when it is extreme enough to lower the body temperature below 28° C. (82° F.), the effect of which is now fairly well known due to extensive experience with induced hypothermia. Ordinarily, however, the mere exposure to cold aggravates shock or causes it to appear after relatively mild trauma or moderate hemorrhage. The presence of wet clothing adds to the seriousness of exposure to cold.

2. *Severe pain,* when excruciating, is said to be able to initiate shock, which is usually temporary even when the patient faints. When accompanied by hemorrhage, burn, or severe trauma, any degree of pain increases the liability of shock and aggravates its severity, probably by increasing vasoconstriction through sympathetic stimulation. This, when excessive, as discussed below, may increase the severity of shock by leading to a vicious cycle.

3. *Duration* of shock without treatment unquestionably aggravates its severity and makes the prognosis more grave. Any patient left in a condition of severe shock for as long as 12 to 24 hours can seldom be saved because the shock becomes irreversible and no form of treatment is effective.

4. *Anoxia* from any cause not only may precipitate circulatory failure but always contributes to its severity. Anoxia usually follows any type of respiratory impairment, including postoperative pulmonary complications, many of which are due to improper anesthesia. Since anoxia is actually produced by impaired blood flow and aggravated by excessive vasoconstriction, which increases capillary permeability and causes a further loss of fluids, a vicious circle may thus be set up.

5. *General anesthesia* always produces an added risk when administered to a patient in shock by increasing its severity. The depressing influence of ether on the blood pressure in shock has been demonstrated experimentally. Although nitrous oxide does not have this influence, it may be harmful for other reasons, particularly when given with a low percentage of oxygen. Any anesthetic leading to anoxia is, of course, distinctly to be avoided. The safest anesthetic for the shock patient is some form of regional or block anesthesia, provided it will meet the requirements.

6. *General factors* may play an important part as contributing to the severity of shock. Females are able to stand much greater losses of blood than males. Even in shock without hemorrhage, females are probably more resistant. Advanced age, the presence of other diseases—especially malnutrition, hypopro-

As to the speed of blood loss, time for compensatory restoration of plasma volume is important. Thus small intermittent hemorrhages are better tolerated than single large ones. However, a single large hemorrhage may seem well tolerated, but actually may lead to *a condition in which shock and even death* may follow a subsequent but small hemorrhage.

A large and rapid loss of extracellular fluid alone (other than blood) may lead to shock. This is undoubtedly an important cause of shock in severe burns, especially those in which hot water or oil or a flash comes in contact with a large area of the skin, producing *extensive edema and/or a large, discharging* wound. Some plasma is also lost and some red cells are destroyed, so that blood loss plays an important part. In extensive thrombophlebitis of sudden development, especially after operation, with or without loss of blood, or in the rapidly forming edema of an entire extremity due to a severe insect or snake bite, or in the crush syndrome, shock *may also occur for the same reason.* The volume of fluid lost into even one lower extremity may approach 4 or 5 liters. Loss of gastrointestinal secretions alone—if profuse and rapid enough, as in severe cholera—may also lead to shock. This loss may be to the outside through vomiting, diarrhea, or fistula, *or may be retained in dilated obstructed loops* of intestine. These conditions have, in common with hemorrhage, the inevitable fall in blood volume which undoubtedly is the reason for the peripheral circulatory impairment or failure.

2. **Severe Tissue Damage.** Without other factors, tissue damage may of itself produce shock (Fig. 2) entirely apart from the loss of extracellular fluid and blood into the damaged *area, even though the latter* is usually present and plays a decisive part. The mechanism is not always clear, but in some cases may have something to do with altered cell permeability, permitting the entrance of sodium and the escape of potassium from the intracellular space. In many instances, the existence of bacterial growth seems to be important by yielding products which impair the *peripheral circulation. This is certainly* true of strangulation of the intestine and in fulminating infections, often called "septic shock." Invasion by bacteria into normal tissue, producing similar toxic products, may also occur as a result of shock itself, thus leading to a vicious cycle aggravating the peripheral circulatory *impairment. The part played by the* rapid breakdown of extravasated red cells through the production of such toxic substances of catabolized hemoglobin as ferritin may also be significant. The mechanism in this group of clinical causes of shock may be due to the action of "toxic" and/or neurogenic factors leading to a decrease of peripheral blood flow through an increase in the blood bed, as discussed below.

3. **Nerve Disturbances.** Brain damage itself is sometimes associated with shock. Severe pain alone or intense emotion seldom

Fig. 2. Typical fall of arterial blood pressure after crushing muscles of the thigh in an experimental animal. (From Cannon, W. B. Traumatic Shock, D. Appleton-Century.)

tailed information should be recorded and, when summarized later, will be of tremendous value, not only in increasing our knowledge of shock but also in evaluating various methods of treatment (3).

Many confusing clinical manifestations of shock may also be clarified by referring to the definition of shock mentioned above and searching for the consequences of the impairment in the peripheral circulation. Perhaps a better description would be "impaired blood flow" or "a decrease in the amount of blood supplied to a given tissue." Important in this connection is the ability of the body to vary the blood supply to individual systems or organs. This occurs by a process known as *selective vasoconstriction*. Thus the extremities, which tolerate loss of blood rather well, may be deprived of much of their normal blood flow in order to conserve the remaining blood volume for more essential tissue such as the brain and the kidney. This vasoconstriction will be evident clinically in the form of cold, bloodless extremities. When the vasoconstriction affects the renal arteries, temporary renal impairment may occur, which indeed may be so severe as to lead of itself to further difficulty in terms of renal insufficiency. If severe, the hepatic circulation may be impaired, evidence of which has been obtained clinically, after hemorrhage in terms of hepatic function tests, and experimentally (4), by finding an increased blood ammonia level in hemorrhagic shock. Finally, vasoconstriction of the vessels supplying the brain may produce sufficient anoxia to lead to sensorial changes which, of course, is a serious manifestation of shock even in the absence of brain damage, because the nervous tissue is particularly sensitive to slight degrees of circulatory impairment or reduced blood flow.

1. The *general appearance* of the patient in severe shock frequently indicates its seriousness; the features are pinched, eyes sunken, pupils dilated, the lips pale or ashen in color, the forehead covered with beads of perspiration—in short, a picture often spoken of as the Hippocratic facies. The skin is cold and clammy over the entire body, but especially in the extremities and the face. Pallor, coldness, and perspiration are actually due to intense sympathetic stimulation which produces vasoconstriction for reasons already mentioned. While the reduced peripheral blood flow is obvious on inspection, measurement thereof is possible in terms of *capillary refilling time*. This can be done over the skin anywhere by noting the time required to refill a bloodless area produced by pressure of the examiner's finger. A better method is to render the nail bed bloodless by pressure on the fingernail and noting, on release, the number of seconds needed to refill. In the normal, it is less than a second. In severe shock, it may be several seconds.

The skin in severe shock shows a characteristic mottled appearance due to local pooling of venous blood alternating with bloodless areas. This, too, is obviously due to a diminution or even cessation of blood flow through the skin.

2. The *sensorium* may be unaffected, but is usually somewhat obtunded. When shock is severe or critical, the patient may appear unconscious so that if one raises his arm it falls to the bed at once as if lifeless. However, the patient will usually answer questions and complain of coldness, weakness, often of dizziness, exhaustion, sometimes of "deadness" of the extremities. Painful stimuli may evoke a groan or slight defensive movements. In the milder cases, the patient will appear listless and apathetic and show extreme asthenia. In certain patients, on the other hand, the sensorium may be so clear that nurses and interns may not suspect the presence of shock without careful examination. After severe hemorrhage, if sudden, syncope often follows; otherwise restlessness is apt to be a prominent manifestation which, indeed, is often of diagnostic value. Hyperactivity also occurs, but is usually due to such associated disturbances as severe emotion, and, in some cases, to infection and uremia.

3. The *peripheral circulatory impairment* is usually evident on inspection of the skin. The changes, as already described, are due not only to the decreased peripheral blood flow but also to the associated vasoconstriction. The reduced blood flow is also evident by the collapsed condition of the veins. The pulse is often rapid, at a rate of 120 to 140 per minute, of poor quality, soft, compressible, and sometimes thready in character. The pulse may even be impalpable at the

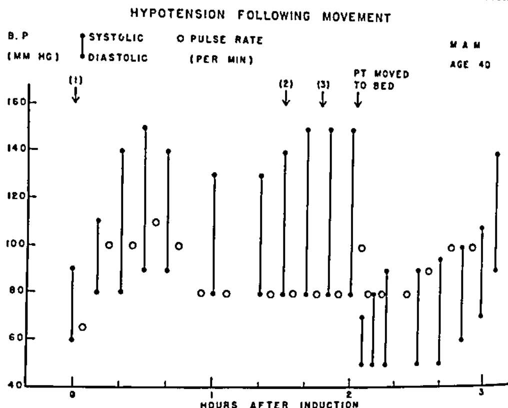

Fig. 3. Hypotension following movement under the anesthetic. While there was a transient fall of blood pressure with the induction of anesthesia at (1), the blood pressure was maintained throughout the operation for repair of a ventral hernia, at closure (2), and at the termination of anesthesia (3). Note the precipitous fall in blood pressure after the patient was moved from the operating table to her bed. There were no other signs of shock. Note that the pulse rate remained unchanged. No treatment was given and the pressure returned to normal within an hour. Although this type of hypotension is usually of little clinical significance and in this case did not jeopardize an uneventful convalescence, it should be avoided by more care in moving patients.

A more severe, prolonged, and dangerous fall in blood pressure usually follows a change from the supine to the so-called "jackknife" position during an abdominoperineal resection of the rectum. Few surgeons now use this change of position but perform the perineal part of the operation either by turning the patient on his side or by merely elevating and spreading the patient's legs while still supine. (From Elman, R. Surgical Care, Appleton-Century-Crofts.)

teinemia, and anemia—generally lowered vitality, and other factors have an obvious bearing on the likelihood and severity of shock.

During operation, numerous factors besides blood loss may lead to shock. One of the most serious, but fortunately not the most common, is coronary occlusion. Any one of numerous anesthetic complications including too much anesthetic, hypoxia, and hypercarbia may be the primary factor. Pronounced change in position may occasionally lead to a sudden unexplained fall in blood pressure (Fig. 3).

THE CLINICAL MANIFESTATIONS OF SHOCK

In a typically severe case of shock, the clinical manifestations, as listed below, are fairly easy to describe. In any given case, however, there are a number of factors which may lead to confusion. Many of these confusing factors are due to variations in the clinical causes of shock or, more often, to the rapid changes which may occur from hour to hour or even from minute to minute. These changes apply to all of the clinical manifestations, including especially blood pressure and pulse rate, upon which great reliance is placed too often, especially after a single observation. Surgical shock is really a *dynamic disturbance* due to rapidly changing stimuli and evoking rapid changes in response. For this reason alone, it is nearly always important for one individual to remain with the patient for the sole purpose of observing and recording the changes in the various clinical signs, particularly as influenced by therapy. Such de-

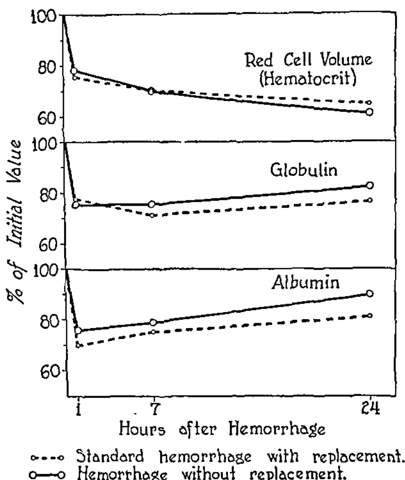

Fig. 5. Blood changes following experimental hemorrhage. A severe hemorrhage (3.5 per cent of body weight) was produced in dogs under local anesthesia and the changes measured in red cells, plasma albumin and globulin. Note the prompt drop at one hour in all three values, indicative of hemodilution with a cell-free protein-poor (i e., interstitial) fluid. Note also the continued fall in red cell volume at 7 and 24 hours, indicating further hemodilution but at a slower rate. Note also that the diluting fluid after the first hour must have contained some protein as shown by the slight increase in the concentration of both globulin and albumin, insufficient, however, to restore the value to normal by 24 hours. The two groups of curves (with and without replacement) refer to the injection of the same volume of isotonic saline to replace the blood removed; whether this was done or not seemed to have only a slight difference in the general pattern of the changes. (From Elman, Lischer & Davey. Am. J. Physio.)

Insufficient data are available to know whether hemodilution after hemorrhage in the human is as prompt and pronounced as it is in the dog The authors have seen a patient hospitalized for treatment of chronic duodenal ulcer with a normal red cell count, show a fall to 2.5 million per cm. within 30 minutes after a severe hematemesis. On the other hand, many patients with known severe bleeding may not exhibit hemodilution for several hours. Hemodilution is probably influenced by many factors, one of which is the giving of the barbiturate drugs which inhibit or prevent hemodilution (in the dog at least) after severe hemorrhage. The important practical application is that one cannot exclude hemorrhage in an acute case just because the red cell count is normal; however, in most cases it will drop eventually.

erally been observed. The value of blood volume measurement as a clinical guide is doubtful, because of difficulties in the technic of accurate measurement and in its interpretation. Blood chemical changes have been thoroughly studied and are similar to those reported for the severely injured. Many of the changes, such as acidosis, are due to a diminished clearance of the acid products of tissue metabolism either at their peripheral site of formation or by the kidneys. The decreased renal blood flow probably also explains the tendency toward an increased blood urea level, although other such factors as an in-

wrist but can be detected over the carotids. In a few cases, however, the pulse rate remains normal. Blood pressure may also remain unchanged for some time, or even may show a transitory rise. Sooner or later, hypotension is shown, although it may fluctuate from time to time. Thus, of all the clinical signs of impaired peripheral circulation in shock, a continuous record of variations in blood pressure probably gives the most accurate information, although single measurements may be misleading. Usually, the diastolic pressure begins to fall before the systolic does. Although the term *shock level* of blood pressure is used, it often is misleading because it varies greatly from one individual to another, dependent somewhat on the patient's normal pressure. For example, a fall in systolic pressure from 150 mm. to 70 mm. of mercury in one patient is much more likely to be accompanied by shock than a fall from 90 mm. to 60 mm. in another. The term *critical level* of blood pressure is also frequently misleading inasmuch as the blood pressure may become immeasurable in patients not actually suffering from shock at all. On the other hand, a patient after severe hemorrhage or trauma usually may show a systolic blood pressure of about 65 mm. of mercury, which might be called a critical level in the sense that any slight additional loss of blood or trauma will be followed by a disastrous decline in pressure. Other features of blood pressure are the rapidity with which the pressure falls and the duration of the lowered pressure. *A low venous pressure* is also present in shock and may be measured with a water manometer but can be readily estimated by noting the appearance and disappearance of the veins as the extremity is elevated or lowered.

4. The *body temperature* may be normal, although a fall of 1° to 2° C. is fairly common and is probably a reflection of the lowered blood flow and the reduced metabolic rate. The *respirations* may be unchanged but are usually shallow and rapid, except in severe hemorrhage when "air hunger" may be present. The latter is probably a compensatory mechanism to overcome the impaired gaseous metabolism resulting from the loss of oxygen carriers in the red cells.

5. *Laboratory examinations* may show a scanty, highly concentrated urine containing no abnormal elements, a normal, increased, or decreased red cell count depending upon the cause of shock (Figs. 4 and 5), and a *leucocytosis* (with eosinopenia due to the stress reaction as discussed in Chapter 12).

Blood volume changes have been extensively studied in shock and a fall has gen-

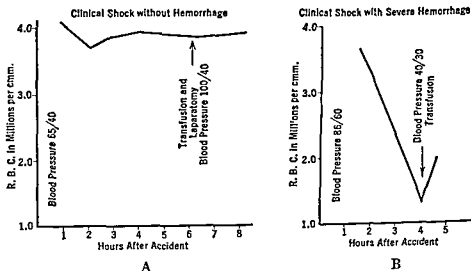

Fig 4. The red cell count (RBC) in shock. A, this patient was shot in several places, including the abdomen, but suffered very little loss of blood; he had all the clinical manifestations of shock. Note the absence of any fall in the erythrocyte count even though parenteral fluids were administered. B, this patient was struck by a street car, which crushed and severed both lower extremities; the loss of blood was considerable. Note the rapid fall in the erythrocyte count, indicating a dilution of the circulating blood. Parenteral fluids were given while the transfusion was being prepared.

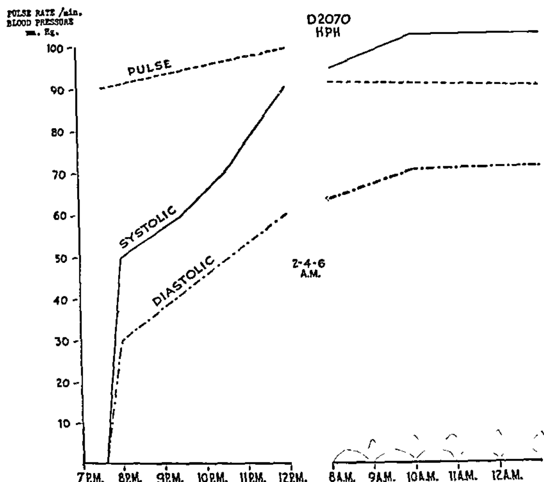

Fig. 6. Neurogenic shock. The patient, a 24-year-old female, was admitted almost at once following an altercation during which she was stabbed in the breast. On admission she was extremely frightened and apprehensive, looked pale, and her skin was cold and clammy. The blood pressure could not be measured but the pulse was slow (90 per minute). However, examination at the time, and subsequently, showed no evidence of loss of blood or serious injury. The laceration of the breast was small and superficial and did not require suture. One grain of codeine was injected, but no intravenous therapy was given. Note the prompt and spontaneous restoration of blood pressure. X-ray was negative and the red count 3.5 million, the white cell count 7,500. The patient was discharged the next day completely well. This might also be called a case of primary shock. (From Homer G. Phillips Hospital, St. Louis, Mo.)

2. The *size of the blood bed* cannot really be discussed without considering the size of the blood volume which fills it. Actually the two usually react in a reciprocal way—a rise or fall in one is accompanied by the same change in the other. Nevertheless, there are many conditions in which blood bed changes occur first, others in which the initial change is in blood volume. It is obvious, however, that with a constant blood volume any sudden increase in the size of the vascular bed, either by widening of the capillary area, including the opening of collapsed channels, or by dilatation of the arteries and veins, or by both, may lead to peripheral circulatory impairment or failure. Such a phenomenon is described as vasomotor paralysis and used to be a popular, but now discredited, theory of the pathogenesis of surgical shock. Nevertheless, there are certain kinds of shock which can be explained only by vasomotor paralysis. One example is the shock sometimes seen after spinal anesthesia, which does actually produce vasodilatation. An increase in the blood bed probably also occurs in the circulatory impairment in nerve disturbances. Another example is the shock in fulminating infections or in other conditions in which

creased breakdown of normal protein tissue, absorption of damaged protein tissue in wounds, and digestion of large amounts of blood in severe gastrointestinal hemorrhage are also responsible. Hyperglycemia is frequent and is due to a mechanism called "traumatic diabetes" or to pituitary adrenal stimulation, the so-called "alarm reaction."

Clinical Manifestations of Hemorrhage. A single severe hemorrhage, especially when it occurs without other complicating causes, usually produces an easily recognizable and characteristic clinical picture. The signs and symptoms, moreover, are often of diagnostic value, which is especially important in the absence of external evidence of loss of blood, as in a bleeding ectopic pregnancy. On the other hand, when hemorrhage is severe enough, particularly when it has lasted for some time or recurred, the peripheral circulatory impairment may become more pronounced and persistent, producing clinical manifestations which may be indistinguishable from those already described.

Extreme pallor, particularly evident in the blanched appearance of the lips and mucous membranes, is characteristic of severe hemorrhage, although cyanosis is occasionally superimposed. The patient may show little apathy but, rather, restlessness and some apprehension unless the hemorrhage is severe. Deep and rapid respirations are more likely, as in thirst, although the latter may be seen when the loss of fluid is not blood but rather interstitial fluid. Laboratory findings characteristic of severe loss of blood tend to be those of hemodilution. The red cell count falls, as does the hemoglobin concentration and the hematocrit, as well as the specific gravity of the whole blood, including the plasma protein concentration. These changes usually promptly follow severe loss of blood and are obviously due to passage of relatively protein-free interstitial fluid into the blood stream from the extracellular as well as intracellular space. The mechanism may be explained on the basis of Starling's hypothesis, which states that the colloidal osmotic pressure of the blood is balanced against the capillary pressure in maintaining the normal interchange between the blood and the interstitial tissue. Thus, severe hemorrhage, by inducing a fall in capillary pressure, leaves an unopposed colloidal osmotic pressure which acts to draw fluid into the blood bed. Indeed, hemodilution in severe hemorrhage may offer a striking contrast to hemoconcentration seen in other types of surgical shock and doubtless explains the greater pallor after bleeding. However, when circulatory impairment after an especially severe hemorrhage is severe and persistent, hemodilution as well as many of its manifestations may be partly or completely inhibited.

PATHOGENESIS OF SHOCK

Only the known clinical features have thus far been presented without definitely stating what their mechanisms are. What produces the profound impairment of the circulation is a question which can readily be answered in most cases (e.g., hemorrhage), but not in all. Answers may be found in the literature which have evoked endless discussion and have been responsible for a number of theories of shock. A toxic theory, an anemia theory, an acapnia theory, a neurogenic theory (Fig. 6), are but a few of those propounded. A complete and critical review of these theories has already been referred to (1). Here an attempt will be made to answer the above question with reference less to theories than to general physiologic mechanisms, particularly as they may be useful in outlining treatment.

Impairment of the Circulation. The circulation may be impaired by failure in one of the three main mechanisms which maintain it. These are 1. the force of the heart beat; 2. the size of the vascular bed; and 3. the blood volume, each of which will now be discussed.

1. The *heart* may fail as the result of myocardial infarction, and peripheral blood flow then falls, just as the flow does in a water system when the pump fails. However, this is not the case in surgical shock, in which cardiac function is normal. In cardiac failure the venous pressure is high; in shock, it is low. Respiratory changes are more likely and more pronounced in the circulatory impairment of cardiac disease. Nevertheless, the novice may mistake a coronary occlusion for surgical shock. This is decisive lest he make the disastrous mistake of giving intravenous fluids in the former which, of course, would greatly aggravate cardiac embarrassment.

due to a fall in blood volume due to increased capillary permeability.

The capillary wall represents the only real permeable link in the entire vascular chain. Thus, a change in permeability may lead to spontaneous alterations in blood volume. Increases in blood volume may occur by passage of fluid from the interstitial space into the blood stream, or decreases may occur by passage of fluid from the blood to the tissue spaces. Moreover, the capillaries themselves may dilate and contract, as do the arterioles and venules, thus also influencing the size of the blood bed. Much less is known of the behavior of capillaries than of the rest of the vascular tree. This may explain the fact that, in spite of the theoretical evidence just mentioned in favor of a general increase in capillary permeability during extreme vasoconstriction, few experimental studies have shown that this actually does occur (see below).

The role of vasomotor changes in shock is of more than theoretical significance. With their advent, the therapeutic application of long-acting vasoconstrictors and vasodilator drugs offers many opportunities not realized before. The selection of one or the other must be based on the need for combating excessive and undesirable vasodilation or vasoconstriction respectively.

Irreversible Shock. This term, widely used, is clinically important largely to emphasize the need for urgency in treatment. Death is inevitable in shock whenever the impairment or failure of blood flow has resulted in the death of vital tissues. Of all tissues, the central nervous system is, of course, the most sensitive to changes in blood flow; the cause of death in surgical shock may be said to follow severe impairment in the flow of blood through the brain. During surgical shock, as already mentioned, the body makes every effort to conserve what little blood there is for the central nervous system by selective and regional vasoconstriction. As long as this is possible, the patient is able to live. Next in importance to the ischemic changes in the brain are similar changes produced in the liver and the kidney. Even though the rest of the body tissues are less sensitive to a deficient blood flow, irreversible changes may occur when the circulation is impaired long enough for the capillary walls to become completely and permanently permeable. When this occurs, the circulation cannot be restored even with copious transfusions, for the capillary bed has lost its capacity for retaining within its lumen even normal whole blood injected in sufficient amounts to more than replace the blood lost. In such a case, the blood generally accumulates in the splanchnic area, where the capillaries are perhaps more vulnerable than in other areas. Irreversible shock, of course, may follow despite therapy because the lesion responsible for shock is not eradicated. This occurs in the presence of a persistently bleeding vessel which remains uncontrolled or when an extensively injured mass of tissue is the nidus for releasing "toxic" bacterial products or the site of continued loss of fluids. Anoxia, as already discussed, is an important factor, producing irreversibility. In still other cases, the factors which maintain excessive vasoconstriction are responsible for the fatal outcome.

These considerations emphasize the one feature of obvious therapeutic importance in shock, and that is the need for removing *all* the primary and contributing causes of shock as *early* as possible. Only if this is done, will restoration of the blood volume lead to a return of the circulation to normal and the maintenance of the blood pressure and blood flow at a safe level.

TREATMENT OF SURGICAL SHOCK

The therapy of surgical shock obviously depends on the nature of its clinical causes and their removal whenever possible. However, certain features of treatment may be applied to all cases regardless of etiology. It should be emphasized, however, that nonsurgical shock, particularly that due to heart failure, must clearly be excluded from most of the following therapeutic measures for reasons already mentioned. Not considered below is the use of cortisone in anaphylactic shock or in shock due to adrenal insufficiency. Septic shock, controllable in part by the use of properly chosen antibiotics, should also be mentioned as another type of therapy not discussed below.

1. Prevention of Shock. Prophylaxis applies largely to the trauma intentionally inflicted during operations. This includes care-

"toxic" absorption is supposed to occur. In the patient suffering peripheral circulatory impairment following spinal anesthesia, the clinical picture is, of course, not typically that of shock for the extremities are warm and dry in contrast to the cold, moist skin in surgical shock. Nevertheless, the fall of blood pressure in spinal anesthesia may be alarming and, indeed, may be fatal. In this and in other conditions where neurogenic or toxic factors are prominent, the fact that such vasoconstrictor drugs as levophed have proved valuable seems to indicate that an increase in the blood bed is the primary reason for shock. Moreover, it is important to know that vasomotor paralysis actually does occur in some cases, lest the common mistake be made of using such a drug for other hypotensive conditions in which the fall in blood pressure is due to loss of blood, and in which, indeed, there may be already excessive vasoconstriction.

In most cases of surgical shock, vasomotor paralysis is seldom present. Instead, definite and even excessive vasoconstriction is the rule. This important observation was made in 1909 by Seelig and Lyon (5) and has been confirmed by many observers since, as discussed at some length in the classic text of Cannon (6), years ago. It will be discussed in some detail after the next section.

3. The *blood volume* is of obvious importance in maintaining the integrity of the circulation. Reduction in blood volume is perhaps the most important mechanism in the pathogenesis of the circulatory impairment seen in most cases of surgical shock. Moreover, it is the easiest one to understand. In hemorrhage, for example, the immediate reduction in blood volume is obviously equal to the amount of the lost blood. In extensive crushing injuries much serum and blood may also escape by extravasation into the tissues, without obvious hemorrhage. It may, indeed, be great enough to produce circulatory impairment without resorting to theories of toxic absorption or vasomotor paralysis. The same applies to loss of extracellular (and intracellular) fluid into and from large burns and large areas of inflammatory edema, and even sometimes is seen in diarrhea if the process is rapid and extensive. These important observations have been made by many observers and have been well summarized by Blalock (7). Indeed, Blalock has also shown that even during abdominal operations there is a considerable exudation of plasma and other fluids, imperceptible perhaps, but which may actually be sufficient to lower blood volume and thus lead to shock.

In certain types of shock, notably shock due to anaphylaxis, to adrenal insufficiency, and to fulminating infection, the cause of the peripheral circulatory impairment or failure may be due either to an increase in the blood bed or to a reduction in blood volume, or perhaps to both. Vasomotor reactions in shock, as mentioned above, are so important that they will now be discussed separately.

VASOMOTOR REACTIONS IN SHOCK. Vasoconstriction, which affects arterioles and even capillaries, is undoubtedly a normal reaction to any sudden loss of blood or reduction in blood volume from other causes. This adjustment in the size of the blood bed downward in response to a reduced blood volume thus maintains blood pressure and blood flow. It does so, moreover, in a regional manner by selectively shunting what blood there is to more vital tissues at the expense of those less vulnerable. For example, vasoconstriction is usually intense in the vessels supplying the skin and the extremities, so that blood may be transferred from the periphery to the liver, kidneys, and especially to the central nervous system.

Excessive vasoconstriction, when it occurs, and we know that many compensatory mechanisms do "overshoot," may be of significance in the pathogenesis of surgical shock because, in itself, it may produce an additional spontaneous fall in blood volume. This mechanism is explained as follows: Extreme vasoconstriction inevitably reduces sharply the amount of blood entering the capillaries, thus interfering with normal interchange of fluid across the capillary wall. Indeed, Landis (8) showed years ago that local ischemia and asphyxia due to vasoconstriction increase capillary permeability and allow plasma to pass into the tissue spaces, a process which may be so diffuse as to produce no perceptible evidence of edema. An actual decrease in blood volume has been produced by Freeman (9) as a result of experimental vasoconstriction alone. Adrenal insufficiency may also be

Crush Syndrome, page 256). For this and other reasons, a tourniquet should be employed for the control of bleeding only if other available methods do not suffice and only for short intervals. If the temperature of the part distal to the constriction can be reduced by artificial means, deleterious metabolic changes from autolysis may be minimized. This is seldom possible. In mass casualties, the time of application of the tourniquet should be indicated lest too long a period elapse before definitive therapy, thus endangering the integrity of the limb.

The injection of so-called hemostatic agents to stop internal bleeding is to be condemned; there is no evidence of their value, at least at the time of this writing.

3. **Conservation of Body Heat.** This traditional and time-honored method of therapy is often used to the detriment of the patient inasmuch as the application of heat in shock may actually be deleterious, as shown by Blalock and Mason (10). A common mistake is the wrapping of the injured patient in warm, heavy blankets, even applying external heat, when the environment temperature is normal or high. Excessive application of heat produces cutaneous vasodilatation, which is harmful because it withdraws blood from vital tissues needing it urgently. Moreover, local heat increases tissue metabolism in the skin unnecessarily, producing harmful acidic catabolic products. Finally, in profoundly depressed patients there is always the hazard of producing a burn with hot-water bottles. Although the patient in shock complains of being cold, it is much safer and just as effective to wrap him in blankets, thus conserving his own body heat, than it is to apply external heat. This is particularly important when the patient has been exposed to cold which, as already mentioned, unnecessarily increases the already excessive peripheral vasoconstriction. It is also important that cold, wet clothing be removed at once and replaced with a warm covering or blankets, not only over but under the patient.

4. **Rest.** Immobilization of the injured part is obviously necessary. The horizontal position, preferably in bed, is also mandatory. Indeed, any movement of the body, as already mentioned above, may prove harmful. The position of the patient with his feet elevated and head lowered is so universally used that it is called the *shock position* (Fig. 8) and is readily achieved by placing blocks of wood

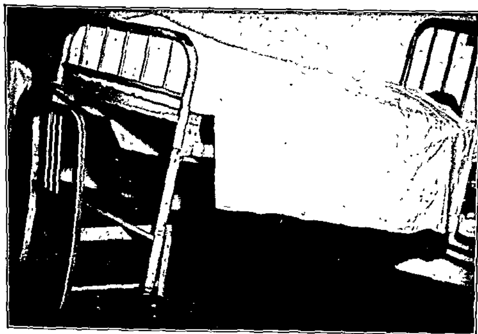

Fig. 8. Bed in the "shock position"; instead of shock blocks under the feet of the bed, a chair has been used.

ful preoperative preparation. It implies the gentle handling of tissues, complete hemostasis, replacing large blood losses as soon as or immediately after they occur, a minimum of exposure of viscera to the air, the control of the patient's apprehension and pain, careful anesthesia, and finally, proper postoperative care. These details are all described elsewhere. It is important here to emphasize the fact that, if these precautions are followed, seldom will the surgeon encounter postoperative shock.

Avoidance of delay in the treatment of injured patients in general will minimize greatly the incidence as well as the severity of shock. Even when shock is not present, undue delay in treatment may permit it to develop. When shock is already present, prompt therapy may halt its progress and promote its disappearance. Extremely important is the avoidance of unnecessary and rough movement of the patient as, for example, from bed to table or vice versa after operation or severe injury. Significant and sometimes alarming circulatory impairment will follow such movement.

2. **Control of Hemorrhage.** The removal of the cause of hemorrhage is obviously indicated in order to prevent further loss of blood. Often, however, when the patient is seen by the surgeon, bleeding has already stopped. The various methods of controlling hemorrhage are described in Chapter 14.

Cessation of bleeding is aided by several natural, spontaneous mechanisms. The drop in blood pressure itself frequently is sufficient to stop further blood loss even in moderate hemorrhage when the vessel is not too large. Such local factors as contraction of the severed vessel, the development of thrombokinase from torn tissue (especially in parenchymatous organs) to promote clotting, and the development of a hematoma which, by its pressure, compresses the bleeding point are also favorable in stopping further loss of blood. Finally, there is a mechanism which increases the clotting power of the blood as hemorrhage continues, due presumably to an increased production of fibrinogen which spontaneously decreases the clotting time, thus tending to stop the leak with a thrombus.

A tourniquet is probably one of the oldest methods of controlling hemorrhage from an extremity (Fig. 7). It is now known that severe systemic effects are, unfortunately, likely to follow the release of a tourniquet which has been left in place for several hours (see

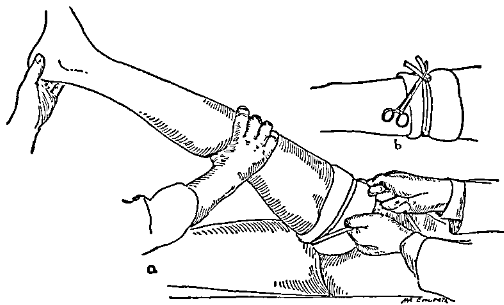

Fig. 7. The proper method of applying a tourniquet to the upper thigh in severe hemorrhage from the lower extremity. a, Application of the rubber tubing with sufficient force to obliterate the femoral artery. A counter force against the knee is exerted by an assistant. The limb is elevated during this procedure. b, Tourniquet in place with a clamp to insure against its becoming loose. Note the towel beneath the tourniquet to insure against injury to soft tissue. This is especially important in the arm where the nerves are less completely protected by overlying muscle and hence are injured more readily.

though saline solution is still the simplest and most effective, and is readily available for use in such cases, it is true, unfortunately, that the results, though beneficial, are usually temporary (14, 15). This is shown by the fact that the rise in blood pressure is transient, because the injected fluid does not remain in the blood stream but gradually filters out through the capillary wall into the tissue spaces. This may be due partly to the increased capillary permeability, as already mentioned, particularly when there has been gross capillary damage. Just as important, however, is the fact that saline and glucose solutions contain no colloids and only colloids are able to remain within the intact capillaries, the walls of which act as semipermeable membrane through which crystalloid can readily pass. Much of the normal function of the large protein molecule of the plasma is, indeed, due to its colloidal property, as originally described by Starling, and is the basis for his hypothesis, first recorded nearly 50 years ago but still known to be important in the treatment of shock.

Whole blood transfusions are widely and effectively used as the best method of restoring blood volume after hemorrhage. The increased availability of blood banks have made this advance possible. The amount of blood required is often large, depending, of course, upon the amount that has been lost. In the severely injured in which blood loss is continuing, many liters may be necessary during operations performed for the control of hemorrhage (16, 17). Usually at least 20 ml. per kilogram of body weight is needed as the initial dose. In the severely shocked patient, several veins may have to be used simultaneously. Even the intraarterial route may be indicated in special cases when the intravenous channel fails to restore the circulation.

When blood is not immediately available, or when some time is necessary to properly type and/or match the blood, blood substitutes may be necessary. In emergencies of this kind, the time factor may be so important that restoration of blood volume by any method may prevent irreversible shock. Solutions containing salt in such a case are better than those with glucose, since the latter is rapidly metabolized. For reasons already mentioned, however, a colloidal solution is even better. The most widely used at present is a substance, first devised and used in Sweden, called *dextran*. Such substances as acacia, periston, and pectin have the disadvantage of not being metabolized by the body, since they are really foreign bodies. Dextran, on the other hand, is a large molecule composed of glucose; gelatin is a protein molecule containing only amino acids; both are normally metabolized. For a single injection, dextran or gelatin solution may be advisable when blood is not available or is being prepared. These solutions, moreover, will be found to conserve blood in the vein because a few cases will respond so well that further infusion will be unnecessary. Dextran, as manufactured in this country, should, however, be used in amounts not exceeding 1 liter. Larger infusions have been observed to provoke capillary bleeding, a complication which has not been reported following large infusions of Swedish dextran.

Plasma is perhaps the best whole blood substitute and has the advantage over whole blood of greater convenience, because it can be stored longer and requires no typing. Pooled plasma, however, has an increased hazard of transmitting homologous serum hepatitis, the incidence of which is appreciable, especially in some parts of the country. However, storage of plasma at room temperature has been shown to reduce or eliminate this danger (Allen, 18). When plasma rather than blood has been lost, the former is preferable. Pure serum albumin is also available as a concentrated 25 per cent solution and is, perhaps, the best blood substitute of all.

Solutions of electrolytes are specifically indicated when the fall in blood volume is not due to loss of blood but to loss of extracellular and intracellular fluid. Various causes for the loss of extracellular fluid have already been discussed. Only when the loss is severe and rapid does shock follow, yet in such a case blood would not be effective and might, indeed, be harmful in instigating pulmonary edema. Replacement therapy would, in such cases, mean adequate infusion of salt solution or, better still, physiologic salt solution, often called "balanced Ringer's solution." Since in these cases some blood or plasma

(shock blocks) under the foot of the bed. The value of this position is probably due to the conservation by gravity of blood otherwise stagnant in the extremities, thus helping to overcome cerebral anoxia. It has, however, the disadvantage of impairing respiration by pressure of the abdominal contents on the diaphragm.

Posture is so important in shock that it has even been used in the diagnosis of the severity of occult hemorrhage. If a patient who has suffered internal gastrointestinal bleeding is allowed to sit up in bed, an increase in pulse rate or a fall in blood pressure is supposed to indicate a severe rather than a moderate hemorrhage.

5. **Relief of Pain.** Since pain is one of the contributing causes of shock, relief of pain is a sine qua non. The pain in fractures is best treated by immediate immobilization and traction. In the extremities, a Thomas splint is perhaps the best method and, indeed, during World War I these splints were applied in the field. It was noted that their use was a most important factor in reducing the incidence of traumatic shock (Cannon).

Drugs, especially morphine, should be used for the relief of pain only when pain is definitely present. Of interest are the observations of Beecher (11), who, in World War II, found that but 20 per cent of freshly wounded patients were actually in pain. For them, the barbiturates were usually sufficient to allay restlessness and to control apprehension. Such sedation prevents movement which might increase bleeding by discharging clots or by interfering with their formation. Morphine, though indicated for severe pain, should be withheld in any patient with a head injury or an intraabdominal lesion because of its tendency to mask symptoms and thus to interfere with diagnosis and treatment. Morphine, moreover, should not be given in the presence of pulmonary disease because of its depressive action on respiration.

6. **Increase of Blood Volume.** The important basic aim in the therapy of shock is to improve the peripheral circulation by increasing blood flow (12). This means, in most cases, a prompt and permanent increase in the blood volume unless, of course, such improvement is evident as a result of the methods already mentioned. In the presence of an inaccessible or immediately uncontrollable source of hemorrhage, however, the method used to increase blood volume, such as transfusion, may be ineffective or only temporarily effective because of continued or recurrent hemorrhage, for which an operation may be indicated. This problem is discussed below.

While the *blood volume* may increase spontaneously, especially after hemorrhage, by the passage of fluid from the interstitial spaces into the blood stream, this process, called hemodilution, necessarily leads to anemia and hypoproteinemia. If the bleeding stops, if the anemia is not too great, and if there is no further disease, this compensatory mechanism is adequate, for eventually the lost hemoglobin and plasma protein are regenerated from food without special therapy. Nevertheless, it is important, even in the acute phase, to maintain a good fluid and food intake. As early as World War I, and perhaps earlier, it was often noted that shock was much less likely to occur in soldiers having access to plenty of water than in those deprived of water, other things being the same. Oral administration of fluid is, therefore, extremely important in the treatment of shock except, of course, when contraindicated by the presence of intraabdominal disease. Under these conditions, the parenteral route must be used to prevent dehydration. More commonly, the parenteral, particularly the intravenous, channel is necessary for the restoration of blood volume critically low and not restored spontaneously. Indeed, in such cases the need for increasing the blood volume may be so urgent that speed becomes a sine qua non inasmuch as shock allowed to persist leads to irreversible changes.

The value of intravenous infusions in restoring blood volume, blood pressure, and blood flow in shock was noted long before the mechanism was understood. As early as 1820, dramatic and undoubtedly accurate observations were recorded showing the benefits following the infusion of saline solution in cholera. Even milk was injected, as well as glucose and sucrose (13). Later, simple solutions were employed instead of blood to replace blood loss after hemorrhage, largely as a matter of convenience and speed, or because of the difficulties and delay associated with the giving of a blood transfusion. Al-

through the capillary walls, leading to a fall in blood volume, activated by hemorrhage into the lacerated tissue.

This well-known initial mechanism is followed, however, by another pathologic change, due to serious renal damage apparently caused by toxins originating from the local area, which occurs a few days later. Blalock (20) has actually demonstrated that the thoracic duct lymph collected after removing animals from a press crushing a lower extremity was definitely toxic when administered to normal animals. Such animals develop hemoconcentration and casts and blood in the urine, and some die as a result of the injection. Bywaters attributed this renal damage to myohemoglobin liberated from the injured muscle, although he felt too that reflex renal arterial spasm was perhaps of greater significance. More recent studies have implicated some of the breakdown products of hemoglobin which apparently are toxic under certain conditions. Ferratin has been implicated (21) as one of the substances normally metabolized in the liver, but in conditions of shock persisting and leading to further circulatory impairment.

Clinical Manifestations. The victim of a crush syndrome while still under the debris may reveal no symptoms of impending shock; the initial pain may even have disappeared. Within a few hours after release of the crush, however, the involved extremity becomes extremely swollen. With this swelling the patient develops all of the signs of shock similar to that of surgical shock due to rapid loss of plasma or to severe hemorrhage. A variable amount of ecchymosis appears over the injured area, depending upon the amount of subcutaneous injury. Fractures or injuries to nerves and other tissues may also be present, and search should be made for them. These patients generally respond to shock therapy, although there is always the likelihood that the infused fluid will continue to enter the damaged limb, increasing swelling, and doing little good in respect to restoring the circulation. A few days later, the manifestations of renal damage appear. Blood, albumin, and casts are found in the urine, later oliguria and finally anuria with resultant uremia develop, commonly terminating in death.

Treatment. The prevention of edema and of serious renal complications demands first priority. It has been recommended that compression bandages be applied to the crushed extremities immediately after the victim is extricated in order to minimize swelling and the escape of infused fluid. The application of cold to the extremity would appear logical theoretically, but Duncan and Blalock (22) have observed that, in animal experiments, this therapy was not effective unless it was started with the onset of decompression. In any case, it is well known that such damaged extremities should be kept cool and not subjected to the harmful effects of heat. Since excessive vasoconstriction is often present, atropine hexamethonium and papaverine have been used. Sympathetic block by paravertebral injection of novocain may be still more effective. Cortisone may be tried. If the trauma is severe, amputation may be imperative.

Crush Syndrome in Other Injuries. A "toxic" factor in the production of shock is now generally recognized, instigated largely by these studies on the crush syndrome. Formerly a "toxic" theory of shock was used to explain all cases. In the case of crush injuries, evidence seems clear that there is such a factor, even though its exact nature is unknown. A similar factor, though of slower development, is probably present in so-called *tourniquet shock*, produced experimentally 30 years ago by Cannon and Bayliss, but studied in more detail in recent years (23). This condition, which may also be seen clinically when a tourniquet is left on for several hours, is associated with the loss of extracellular fluid, plasma, and blood into the extremities as soon as the tourniquet is removed. Although the manifestations of shock may be controlled by adequate replacement therapy, the relief is not complete, suggesting therefore that a "toxic" factor is superimposed upon the lost plasma. Repeated observations in the treatment of war casualties, confirmed by experience in the Korean conflict, have shown clearly that clinical shock developing under such circumstances often responds only slightly to transfusion and that the removal of irretrievably damaged muscle plays an essential part in the control not only of shock but also of renal impairment. Infection undoubtedly plays a part in the relief of

also may be lost, a small amount of plasma or blood should also be given.

The circulatory impairment due to a fall in blood volume may sometimes be improved by a reduction in the size of the *vascular bed.* This may be done by bandaging the extremities, although the clinical results are apt to be disappointing. Vasoconstrictor drugs also may reduce the total blood bed and formerly were used extensively in the treatment of shock. They are now known to be harmful since they increase an already existing, even excessive, vasoconstriction. On the other hand, when surgical shock is due largely to neurogenic, "toxic," or other factors and there has been no loss (or adequate correction of loss) of blood or other fluids, the long-acting vasoconstricting drugs such as levophed (levarterol bitartrate, l-norepinephrine) may have a distinct place in therapy. The dramatic effect of hydrocortisone in combating shock due to anaphylaxis and in adrenocortical failure is not entirely clear. It is likely that its action, however, is in the capillaries, reducing their permeability and thus conserving blood volume.

7. **Operations in Surgical Shock.** A needed operation is, in general, postponed in the presence of surgical shock until this condition is at least partially relieved, in order to avoid the greatly increased risk of adding the trauma of operation and of anesthesia to the effects of shock. Nevertheless, operation is sometimes necessary to prevent or control the actual cause of shock as, for example, the removal of gangrenous intestine. Failure to do so is fatal. A more common example is the need for operation to control internal hemorrhage which threatens life despite nonoperative measures. Such an operation, however, must offer some assurance that the bleeding can be controlled. This is usually possible in ruptured ectopic pregnancy, postoperative hemorrhage, gunshot or stab wounds of the abdomen, rupture of the spleen, and in certain cases of persistent gastrointestinal hemorrhage. The possibility of actually using some or all of the escaped blood by collecting it and reintroducing it into the circulation (refusion, autotransfusion) adds to the advantages of the operation. The risk may be minimized somewhat by choosing an anesthetic that will not increase anoxia. Transfusions should, of course, be started before and maintained throughout the operation. Delay in operation for internal bleeding is indicated when there is good evidence of a spontaneous cessation of the hemorrhage.

Operation for the removal of badly damaged and necrotic tissue is obviously urgent, but may await control of the initial shock following the injury. However, the role of necrotic muscle is so important in promoting shock that long delay in its excision is unjustified. This is especially true inasmuch as devitalized tissue may be a nidus for serious infection or may play an important part in initiating and maintaining renal impairment.

8. **Oxygen.** Insofar as anoxia occurs in shock, inhalation of oxygen would seem to be of some value. On the other hand, the arterial blood is usually saturated normally in surgical shock. Nevertheless, oxygen inhalations have proved beneficial, particularly when respiratory difficulties are present. The gas is given in high concentration (95 per cent with 5 per cent CO_2). Avoidance of carbon dioxide accumulation is, of course, also important.

CRUSH SYNDROME

The so-called crush syndrome has an interesting history and many implications in the therapy of shock, even at the present time, and is therefore considered under this separate heading. Crush injuries are seen commonly during wartime, not so much in military personnel, but among civilians after they have been extricated from beneath the debris of bombed buildings. Many such victims were seen and studied during the London blitz by Bywaters and others (19). Much of the information concerning the crush syndrome has application to tourniquet shock, which is described later, and extensive muscle damage from penetrating missiles of any kind.

Pathogenesis. The initial shock seen in these crushed individuals is readily explained by the fall in blood volume from the loss of extracellular fluid, blood, and plasma into the injured area. The crushing of the tissues produces obvious damage and anoxia, which increases capillary permeability. However, it is only after the victim is extricated that the circulation returns; the fluid then is lost

14

WOUNDS

Wounds may be inflicted accidentally or produced by the surgeon to correct a disease process. Those produced by the surgeon are comparatively simple, whereas those inflicted accidentally may be so extensive and damaging that they may kill the patient. Although industry is constantly adding safety factors to reduce incidence and severity of injury, the human being himself is showing very little ability to reduce injury for which he is primarily responsible. For example, in 1958 there were 91,000 accidental deaths and 9,100,000 disabling injuries in the U.S.; of this group, 37,000 of the deaths and 1,350,000 of the injuries were caused by automobiles. Not fully appreciated is the fact that 27,000 deaths and 4,000,000 injuries were sustained in the home (data from the National Safety Council). These appalling figures indicate clearly that the care of injuries consumes a huge proportion of the physician's time. Moreover, there is no indication that operations for other surgical lesions are decreasing proportionately. Accordingly, the care of wounds must remain a very important phase of the surgeon's training and life (1, 2).

KINDS OF INJURY

The local response of the body to injury depends largely on its kind and severity. In general the simplest injuries are those which damage cells without impairing their viability, such as a stroke on the skin with a dull blunt object, or a mild scald or sunburn. The more severe injuries cause actual death of cells, called necrosis, or, when the tissue involved is extensive, gangrene. On the other hand, tissue may be divided or separated with very little or no necrosis. Classified according to type, the various injurious agents may be described as follows.

1. *Mechanical* (or *traumatic agents*) are perhaps the most common and vary greatly in degree. Wounds inflicted by mechanical trauma may be of numerous types. They may be closed or open; in general, the former are designated as contusions and the latter as lacerations (Fig. 1).

2. *Chemical irritants* are often inadvertently used in salves and solutions; especially dangerous are those containing phenol which

Fig. 1. Traumatic injury. Two deep lacerations of the scalp sustained during an auto accident. Severed temporal muscle can be seen in the lower part of the posterior wound.

such "toxins," as shown by the beneficial effect of chemotherapy (24, 25).

A similar mechanism may occur in certain extensive burns in which moist, necrotic skin forms and, on disintegration, produces by autolysis certain products which, by absorption or otherwise, produce signs of toxemia. The same is true of strangulated intestine. In any case, there seems to be no question that there is indeed a "toxic" factor in any patient suffering from shock associated with extensive tissue and particularly muscle damage, even though there may also be a great loss of fluid, including blood or plasma, into the damaged area.

The practical application of these findings seem clear. One cannot treat shock by single methods of therapy. In many cases a combination of methods is necessary—as blood transfusion and operation for the control of bleeding, both of which may be necessary for the removal of necrotic tissue as well as for replacement therapy in the crush syndrome.

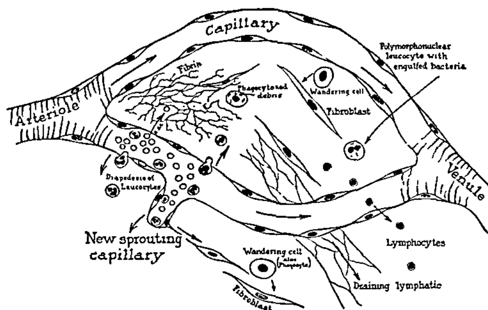

Fig. 5. Diagram illustrating the main histologic features of inflammation and repair.

energy, and stimulate the anterior pituitary to secrete ACTH (adrenocorticotrophic hormone) and STH (the somatotropic hormone). The adrenal cortex is activated by ACTH to secrete gluco-corticoids, such as cortisone, and by STH to secrete mineralo-corticoids, such as desoxycorticosterone. This stage in response may be classified as the *stage of resistance.*

As noted above the reactions involved in the alarm reaction observed in trauma are equivalent to the various responses induced by ACTH. These reactions are numerous (3); many appear to be detrimental to the body (4) and probably are. There is a retention of sodium chloride and water, but potassium and calcium are excreted in increased amounts. There is an appreciable negative nitrogen balance, a deleterious effect of trauma first emphasized by Cuthbertson (5) years ago. Utilization of carbohydrates is decreased by an anti-insulin effect. There is an increase in the urinary excretion of 11 oxysteroids and 17 ketosteroids. An eosinopenia is fairly constant.

The process of *wound healing* may be divided into three phases: 1. the initial or lag phase; 2. the phase of fibroplasia; and 3. the phase of scar contraction. One of the first local reactions to trauma is the deposition of an exudate (serum, blood, and lymph) which usually clots, except when accumulating in large quantities. The process of removal of dead tissue cells is necessary to wound healing and begins almost immediately after the injury. Phagocytic cells including leukocytes, histiocytes, and macrophages are brought to the wound by an increased blood supply (Fig. 5). These cells are aided by enzymes, mostly of the proteolytic type, which dissolve dead cells either inside or outside the phagocytic cells. By the second day there is a proliferation and migration of endothelial capillary buds into the blood clot. Proliferation of fibroblasts from the wound edges is profuse. The product of humoral and cellular response just described is called *granulation tissue* (Fig. 6); it is necessary to the healing of all wounds. The aging process of granulation tissue is dependent upon the fibroblasts. These cells secrete collagen (a protein) which produces strength in the adhesion between the wound edges. The old collagenous connective tissue at the edges of the wound fuses into the new collagenous tissue by contiguity of cell growth and development of collagen fibrils. The tensile strength of the wound is dependent primarily upon the collagen rather than on fibroplasia per se (6). The appearance of collagen fibrils (about the sixth day) in the granulation tissue represents the end stage of the lag period when tensile strength is lacking.

Fig. 2. Chemical injury. A spreading ulcer of the leg developed in this patient after a simple laceration was treated by repeated application of a salve containing phenol. Rapid healing followed cessation of the chemical irritation.

produces definite cell injury and in some cases actual death of tissue (Fig. 2). Ordinarily, the serious chemical injuries are due to accidental contacts with strong acids, alkalis, liquid bromine, and similar agents which destroy the tissue with which they come in contact. Insect and snake bites are often serious because of the introduction of toxic chemical substances which injure cells directly.

3. *Radiant energy* such as heat and also x-ray and radium have the power to incite an inflammatory reaction and, if severe, actually to kill tissue. Atomic energy has introduced a new combination of heat and radioactive injury. Electricity of high amperage not only can burn tissue but also may coagulate cytoplasm and thus kill cells immediately. By

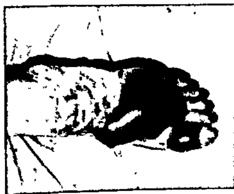

Fig. 3. Thermal injury. This blister has the same appearance as if caused by excessive heat. Actually it was produced by excessive exposure to severe cold; it represents an injury due to frostbite.

Fig. 4. Bacterial injury. Local necrosis caused by a staphylococcus infection (furuncle) which has already opened and discharged its content of pus.

chilling, cold can injure tissue (Fig. 3) and, by freezing, can actually kill it. The effects of these agents will be described in Chapter 16.

4. *Pathogenic bacteria* and their products of growth or disintegration are far and away the most important and most frequent agents capable of inciting the inflammatory reaction, acting not only as the primary agent, but more commonly entering the field after other agents have started the injury (Fig. 4). Bacteria, of course, not only damage cells but are capable of provoking extensive necrosis, and frequently invade the entire body and challenge life itself.

HEALING OF WOUNDS

A wound may be defined as a solution of the continuity of tissue due to mechanical force or related mechanisms. Under the latter factor, thermal, chemical, and bacterial agents are included. Wounds give rise to various reactions in the body which determine the site of healing, final outcome, and so forth.

Physiologic and Cellular Reactions. Most of the reactions to trauma are the result of hormonal response as elucidated by Selye and often spoken of as the *alarm reaction*, which develops almost universally when the trauma is severe. The local nerve endings send stimuli to the autonomic nervous system; these stimuli become amplified in the ganglia and pass through the sympathetic system to the medulla of the adrenal gland which secretes large amounts of epinephrine and norepinephrine. These agents raise the blood pressure, mobilize liver glycogen to provide glucose for

sile strength. However, scar tissue is usually not as resistant to tension as is normal tissue; in fact, when present to excess, it may lead to abnormal stretching and herniation. Contracture of the scar is an important phase of healing. In the first place, it reduces the size of the defect and thus aids the process of epithelization. The contracture is most noted in the longitudinal axis of the wound; it usually takes effect in areas of least resistance thus explaining to a great extent the marked deformity about the eyes, mouth, lips, and flexor surfaces of joints in burns or in other wounds in which massive tissue destruction is present. There is little elasticity in scar tissue. Although scar contracture often results in serious deformity, it does exert some favorable influence. For example, it reduces the size of defects and exerts a squeezing effect on the wound; this compressing effect obliterates the excess capillaries and squeezes out the edema fluid.

Epithelial growth starts almost immediately after injury but not until the dead tissue is removed; thus, epithelization develops earlier in clean wounds than in jagged wounds which have been incompletely debrided. When a defect is present, epithelium will not grow across the intervening clot until granulation tissue has developed and has filled the defect. The primary focus for skin regeneration is from the stratum germinativum.

A crust or scab develops over almost all superficial wounds. To a certain extent, it is part of nature's process of healing. The crust represents dried secretion from the wound and adheres closely to the wound. In this respect, it is protective, since it minimizes bacterial contamination; moreover, it adds to the tensile strength because it is tough and densely adherent. However, on occasions, the crust appears to cover the line of epithelial regrowth so densely that epithelial regeneration may be slowed down. To prevent this the crust may be soaked off. If it is lifted off forcibly, some of the newly regenerated skin may be torn off. When epithelization is complete, a crust will no longer develop.

Abnormal Physiologic Factors Affecting Healing of Wounds. In 1937, Lanman and Ingalls (8) demonstrated experimentally that when the vitamin C content of blood approximated the scorbutic level, delayed healing and wound disruption were common. A low vitamin C reserve is comparatively frequent in charity patients with intestinal diseases such as carcinoma of the stomach. For example, 40 per cent of a series of 90 patients with intestinal lesions (chosen consecutively) at the Illinois Research Hospital had a blood cevitamic acid level below 0.40 mg. per 100 ml. of blood (normal—0.70 to 1.0). This high incidence emphasizes the importance of giving fruit juices or cevitamic acid to such patients. Moreover, Lund, (9) has shown that celiotomies deplete this level still further, at least for a period of four to six days. According to Dunphy and associates (7), the basic defect in delayed healing in vitamin C deficiency is related to collagen synthesis; "mucopolysaccharide production and the formation of reticular procollagen material are not inhibited, and may be considerably increased."

Years ago, Clark (10) and Harvey and Howes (11) demonstrated that in protein deficiency wound healing is impaired. The relationship of tissue and blood protein to wound healing and various surgical complications has been reviewed by Ravdin and Gimbel (12). More recently Udupa and associates (13) have shown experimentally that in hypoproteinemia the "major factors in this impairment of wound repair appear to be the decreased accumulation of mucopolysaccharides and retarded collagen synthesis." When they added methionine to the protein-free diet fed their animals, mucopolysaccharides and formation of new collagen fibers were restored to normal levels.

Types of Healing. The healing of wounds may be classified as *primary* (*first intention*) *or secondary* (*healing by second intention*).

Healing by *first intention* (Fig. 8) takes place in a closed wound and occurs without infection or without secondary opening to remove blood, serum, or other fluid collecting in it. Accordingly, this represents ideal healing, although a mild degree of erythema, edema, or discoloration may be present. These manifestations, including mild induration, are encountered in wounds healing under optimum circumstances. Obviously, residual effects, such as scar tissue and disability, following healing by first intention are minimal or absent.

Fig. 6. Granulating wound after complete "full-thickness" loss of skin. The original injury was a severe burn of the axilla involving all layers of the skin (third degree); the necrotic tissue has already sloughed away. Spontaneous healing is too uncertain and slow in such a wound and skin grafting was done.

Dunphy and associates (6, 7) have shown that during this lag period certain important chemical and histologic changes are taking place. They demonstrated a marked concentration of hexosamine and mucopolysaccharides in the wound during this period. The hydroxyproline content of the wound was very low for three days following operation, but there was a rapid rise between the sixth and twelfth days. Hexosamine may be considered an index of ground substance and hydroxyproline of collagen. From the sixth day onward (in the normally healing wound), tensile strength increases rapidly. The end result of fibroplasia is scar (Fig. 7) or cicatricial tissue which accounts in part for the ten-

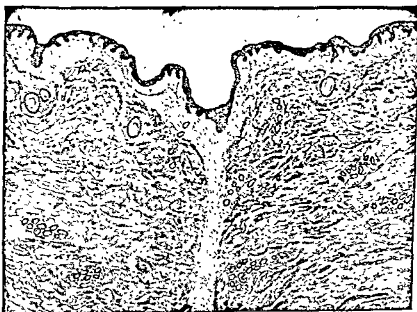

Fig. 7. Microscopic section through a healed surgical incision of the abdominal wall. Note the thin scar binding the two parts of the divided normal tissue. (From MacCallum. Textbook of Pathology, W. B. Saunders.)

Fig. 10. Hematoma of arm and face following a fall three days previously. Left, hematoma of medial side of upper forearm; right, contusion of nose with moderate swelling. As often happens following injury in this area, a hematoma developed under each eye.

frequently erroneously diagnosed as a depressed fracture of the skull. Occasionally a hematoma becomes infected, producing an abscess, but this usually happens when it is associated with a punctured wound; infection, however, may on rare occasions arise from blood-borne bacteria, as illustrated in Figure 11.

The immediate *treatment* of contusions consists primarily of the application of pressure and cold packs to stop the hemorrhage and extravasation. Rest of the injured part is essential to obtain optimum healing. After 24 hours the application of heat will facilitate because it produces an increased blood supply. When the laceration of subcutaneous tissue has been extensive, such as encountered in crushing injuries, extensive contracture due to scar or atrophy of important structures may develop. Wisely supervised active and passive motion may be useful in preventing these complications. When an injury is of the crushing type and severe, the patient should be examined for shock, which is apt to develop very rapidly after the patient is removed from the mechanism producing the injury; therapy is described on page 257.

If a hematoma forms and does not subside within a few days, an attempt should be made to aspirate it. If evacuation is not possible by aspiration, as commonly is the case because a variable amount of the blood is clotted, a small incision (under local an-

Fig. 11. Infected hematoma. This boy sustained an injury to the side of the head in a fall, resulting in a hematoma above the ear. Pain and tenderness decreased, but in two or three days became mildly intensified; doubtful fluctuation but no redness was present. Aspiration of the swollen area yielded pus; incision was carried out as indicated by the dotted line. Culture revealed streptococcus. Infection may develop in hematomas anywhere on the body, but is relatively uncommon; the organisms may gain entrance spontaneously (via blood stream) or through microscopic punctured wounds or lacerations.

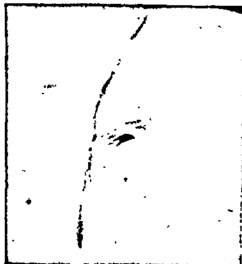

Fig. 8. Healing by first intention. The abdominal incision was made two months previously for the removal of a diseased gallbladder in a 78-year-old woman.

Healing by *second intention* (Fig. 9) is a term used to designate impairment of healing following infection, wound separation, or a collection of fluid which requires surgical opening of the wound. As a consequence of this complication, granulation tissue forms and healing is delayed. Open wounds which are allowed to heal without closure do so by secondary intention regardless of the presence or absence of infection. Fresh open wounds closed by a skin graft can heal by primary intention unless drainage develops spontaneously following surgical opening.

Healing by *third intention* is a term not universally recognized, but which is used to define healing following delayed closure or following application of a skin graft to a granulating surface; the term is applied regardless of the presence or absence of suppuration or drainage.

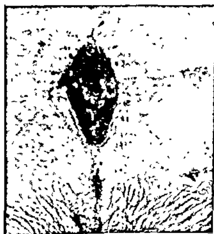

Fig. 9. Healing by secondary intention. The upper portion of a low mid-line incision for the performance of a gynecological operation became infected and is healing by granulation tissue.

TYPES OF WOUNDS

Contusions. A contusion or bruise is an injury of the subcutaneous tissue usually inflicted by a blunt object. There is frequently laceration of the soft tissues beneath the skin, but it may be of microscopic character. The injury of the overlying skin or mucous membrane is usually trivial and not great enough to allow the entrance of bacteria.

The *clinical manifestations* of contusions vary considerably, but in general they are much less pronounced than those observed in open wounds (see page 266). Pain is experienced immediately unless it is masked by excitement, traumatic shock, or unconsciousness. Swelling, tenderness, and ecchymosis are almost constant features of contusions except the minor ones. The pain usually subsides and disappears within 24 hours, except that movements of the injured part may create pain for 7 to 10 days, until healing of the tissues takes place. However, there are many complicating features of severe contusions, such as those produced by fracture and injuries to ligaments (sprains) and tendons, in which pain upon motion may be prolonged for weeks. Blood vessels are invariably severed except in the minor injuries and give rise to subcutaneous hemorrhage. If the hemorrhage arises from small vessels, the blood will infiltrate the tissues, perhaps becoming visible as a "black and blue" spot of the skin; this is known as ecchymosis. If the blood does not infiltrate the tissue but remains localized in a circumscribed manner, it is known as a hematoma. A hematoma (Fig. 10) may be palpated as an indurated or fluctuant area which frequently is absorbed very slowly. The blood may clot but usually remains liquid, day by day becoming darker and more viscid until, after several days, it is so thick that it cannot be aspirated through a needle of the type used in venipuncture (i.e., Nos. 19 and 20). When a subaponeurotic hematoma forms in the scalp, the edges become raised and indurated, and the injury is

tosis and fever will develop shortly after massive wounds are inflicted. Likewise, massive wounds with severe hemorrhage will result in traumatic shock (see Ch. 13) and anemia; the former develops immediately whereas the latter does not develop for 12 to 36 hours because time is required for blood dilution, as discussed in Chapter 13. There may be many complicating features of serious wounds, such as disability and deformity depending upon the structures damaged (e.g., fracture, torn ligaments, and lacerated nerves); the disability may be produced by pain as well as by damaged structures. After repair of the wound, pain usually disappears in 24 to 48 hours, but the tenderness remains for days.

Superficial wounds. Under this heading are included only those wounds which involve the skin and subcutaneous tissue to such a slight extent that suture is not required. Even though all layers of the skin may not be penetrated, a serious and even fatal infection may develop, usually due to a streptococcus and beginning as a lymphangitis of cellulitis. Therefore, the most important element in the treatment is the prevention of serious infections.

Treatment. Because of the danger of serious infection, all superficial wounds should be treated immediately after the injury and as many of the contaminating organisms eradicated as is possible. If a wound bleeds, the blood tends to wash out clumps of bacteria and foreign particles and is therefore an aid to aseptic healing. Local application of antiseptics to open wounds is in general to be condemned because of possible damage to tissue cells.

Abrasions should be washed gently with soap and water if the injured area is dirty. A dry sterile dressing is then applied. Local applications are not advisable except perhaps sterile petrolatum which may prevent the dressing from sticking. Cinders and other particles imbedded in a superficial abrasion may be removed advantageously by scrubbing with a brush after an anesthetic has been administered. This is particularly important when the wound is over the face because it will minimize subsequent cosmetic blemishes.

Superficial and short lacerations may be closed conveniently and the edges approximated by the application of a strip of adhesive tape which has been "flamed." If such a wound occurs on the face, however, it will usually be advisable to apply sutures since less scar will result from the better approximation. Regardless of the depth of the wound, if it is known to contain foreign material it must be opened and the debris removed.

In *punctured wounds* dirt and foreign bodies may be retained because of the small opening and lack of bleeding. These wounds are, therefore, more apt to become infected. Although on certain occasions it might appear wise to open and cleanse them, this is not advised as a routine. Such additional injury adds to the inflammatory reaction and may also spread the bacteria. Moreover, it is known that, after infliction of such a wound, bacteria are taken up by the lymphatics quite rapidly and travel far beyond reach of any antiseptic within a very short time following the puncture. It is *very important that rest be obtained* to combat infection and encourage healing. A punctured wound on the sole of the foot produced by a rusty nail, for example, is much more apt to become infected if the patient is allowed to walk. Punctured wounds in general are most prone to produce tetanus (see Ch. 7); for that reason it is more necessary to give a prophylactic dose of antitetanic serum of at least 1,500 units. It should be emphasized that it is not the rust itself, but the foreign bodies and bacteria on the rusty nail which are responsible for the infection.

Deep Wounds. The most important symptoms and signs of wounds have been discussed earlier in this chapter. However, certain manifestations will be presented in more detail under the various steps in the treatment taken up below; they are, as far as possible, in chronologic order. Before the local wound is repaired, the patient must be *thoroughly examined* for other injuries, some of which may prove much more serious than the local wound. War wounds are discussed in detail in Chapter 42.

TREATMENT OF OPEN WOUNDS
GENERAL PRINCIPLES

To minimize infection and facilitate rapid healing, numerous important principles must be utilized in the treatment of all serious

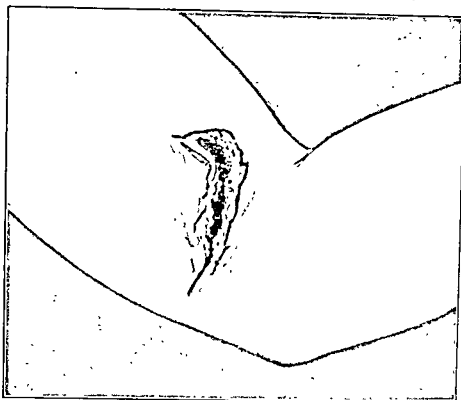

Fig. 12. Deep lacerated wounds of this type are sustained by relatively blunt objects. Because of the jagged edges, traumatized tissue, and contamination, débridement is an important feature in their treatment.

esthesia) may be necessary. After evacuation of the clot, a pressure dressing is applied to eliminate the resultant dead space; it is usually advisable not to close the small incision made for this purpose.

Open Wounds. There are many types of open wounds. An *abrasion* consists of a tearing or cutting of the superficial layers of the epithelium and is associated with an effusion of serum or a slight amount of capillary bleeding. *Punctured wounds* are made by sharp objects and may be comparatively deep, although the surface wound may be very small. *Lacerated wounds* (Fig. 12), are produced by dull objects and present torn and uneven edges. An *incised wound* is produced by a sharp object and presents smooth, even edges. A wound is considered *penetrating* when it enters a body cavity; it is classified as *perforating* when it penetrates the entire body. A *contaminated* wound is one which contains organisms, but in which sufficient time has not elapsed for the body tissues to kill the bacteria or for an infection to develop. Practically all open wounds sustained outside the operating room are contaminated. An *infected* wound implies previous contamination and sufficient lapse of time since injury to have allowed the invasion of the tissue by the bacteria and the development of the manifestation of infection. *Avulsions* are wounds in which a portion of the body has been torn away. The scalp and extremities are most often involved. The edges of such wounds are practically always uneven and jagged, due to the tearing of tissue. When an extremity such as the arm is avulsed, shock may be considerable, but fatal hemorrhage does not always ensue because of the rapidity of clotting in torn vessels. Chemical and thermal agents may also produce wounds which, because of their specific nature, are discussed elsewhere (see Ch. 15). Open wounds may be classified as superficial or deep.

Of the *clinical manifestations,* hemorrhage is perhaps the most important; all open wounds bleed, the amount varying with the extent of the wound and the size of the vessels torn. Tenderness and pain are constant unless masked by excitement, traumatic shock, or unconsciousness. After an hour or two, swelling is manifested; ecchymosis about the wound edges will be variable. Mild leukocy-

13. *Apply Proper Emphasis on Rest.* Although early ambulation after operation is conducive to rapid convalescence in many types of wounds, it does not apply to wounds of the lower extremity. This is due to the impairment in blood flow from the leg when in the dependent position. A patient with a major wound of the leg should not be allowed up until healing is nearly complete.

14. *Utilize Dressings for Specific Purposes.* The purpose of a dressing is to protect the wound from outside contamination and to absorb secretions. Keeping the uninfected wound dry encourages optimum healing. Because of the danger of contamination during a change of dressings, they should be changed infrequently unless pain or unexplained fever develops or they become soiled.

SPECIFIC DETAILS

Under this heading will be included the actual technical procedures utilized in the treatment of wounds; in general they are discussed in the order in which they will usually be employed in practice.

1. *Control of Hemorrhage.* Control of active hemorrhage is so urgent that it usually is a part of first aid treatment. Usually, all that is necessary is to apply pressure or to resort to a gauze pack and apply a light dressing over it. If the bleeding site is in an extremity, elevation thereof will often lead to cessation of the hemorrhage. Pressure over the wound may have to be maintained for several minutes to allow the development of a clot in the lumina of the severed vessels. If the bleeding is an ooze from innumerable points, the application of hot moist packs may be effective. On the other hand, if a large artery has been severed, it will be necessary to isolate the vessel, clamp it, and ligate it (perhaps proximal to the site of laceration) when definitive therapy is being carried out later in the operating room. When large vessels of this type are severed, first aid treatment by a pressure bandage may not control the bleeding. Under such circumstances it may be necessary to apply a tourniquet until definitive treatment can be carried out. To minimize deleterious changes from ischemia it is desirable to release the tourniquet for a moment every 20 or 30 minutes, but this procedure is usually associated with the loss of so much blood that it is inadvisable. However, the *tourniquet will have to be released* at the end of two hours, lest the ischemia lead to gangrene; it should be released only by a physician who should apply enough pressure at the bleeding point to minimize the blood loss during the "flushing" of the limb. A *tourniquet must never be applied* much tighter than necessary to obstruct arterial flow, lest the nerve trunks be injured, thereby resulting in a subsequent paralysis. Whenever convenient, a blood pressure cuff should be used as the tourniquet since the amount of pressure can in that way be controlled accurately. In spite of all precautions *tourniquets are potentially very dangerous* (see also page 252). If ample dressings are available and are applied with the proper amount of tension, a tourniquet need be used only on exceptional occasions. For example, a battalion surgeon (Capt. Lawrence Mann) who went through the bloody attack on Omaha beach on D day in Normandy in World War II found it necessary to use a tourniquet only once during the entire attack which lasted several days. On this one occasion it could have been avoided but was placed at the end of a stump after destruction of the distal portion of the extremity by an exploding shell; used in this way it can harm only the slight amount of tissue remaining distal to the tourniquet.

Although numerous hemostatic agents (fibrin foam, oxidized cotton or gauze, and gelatin sponge) have been made available during recent years, *only one, the gelatin* sponge (Jenkins and associates, 14), is receiving wide usage at the present time. It is used chiefly during major operations when the bleeding vessels cannot be reached for ligation, when its ligation might lead to serious ischemic effects, or when uncontrollable bleeding occurs in parenchymatous organs such as the liver, spleen, or kidney. It should be emphasized that none of the hemostatic agents will control hemorrhage from a large artery but are most useful in controlling mild hemorrhage from inaccessible points or from brain and bone tissue. However, the gelatin sponge is very effective in controlling hemorrhage from large veins. All tend to encourage slightly the growth of bacteria. All are soluble and need not be removed.

wounds. The surgeon must be so familiar with these principles that he utilizes them automatically; failure to recognize the importance of these principles may result in failure, and perhaps even in the death of the patient.

1. *Maintain Aseptic Technic.* All personnel working in or about the operating room must adopt routines and habits which will prevent infection. Caps and efficient masks must be worn at all times by patients as well as by operating personnel. Coughing, sneezing, and clearing of the throat are prohibited in the operating room. The skin must be properly prepared (e.g., soap, water, and alcohol) and draped to exclude skin from the field after the incision is made. Utilization of instruments wherever possible, instead of fingers, for manipulation in the wound will minimize contamination. All personnel should develop an automatic conduct which will abolish breaks in technic (see page 63).

2. *Maintain Gentleness at All Times.* The surgeon must learn to be kind and gentle to tissue at all times, since rough manipulations give rise to hemorrhage, exudation, and infection; even though infection fails to develop, healing is impaired.

3. *Use Small Instruments.* The use of small instruments, particularly hemostats, and ligature of small bites of tissue in tying bleeding points will result in much less trauma to tissue. For ligating vessels some surgeons rely on transfixing sutures which are tied just tight enough to stop bleeding but not tight enough to cause necrosis.

4. *Utilize Sharp Dissection Wherever Possible.* Dissect tissues with the knife, utilizing the scissors or hemostat only when safety indicates. At all times use a knife (not scissors) to cut or trim skin.

5. *Keep Tissues Moist.* When a large amount of raw tissue is exposed, keep a sponge moist with warm saline on the area where the surgeon is not working; this prevents drying, which is very harmful.

6. *Minimize Blood Loss; Replace That Lost.* As the surgeon cuts through the tissue, the assistant must rapidly clamp all bleeding points because the amount lost in the discarded sponges is always greater than anticipated. During recent years it has been demonstrated that liberal replacement of blood loss will permit much more extensive procedures with greater safety than was previously considered possible.

7. *Use Fine Nonabsorbable Sutures Wherever Possible.* All sutures should be as fine as is consistent with the strength required. When a suture fails to hold, it is usually because it has pulled or cut through the tissue and not because it broke. Nonabsorbable sutures incite much less tissue damage than catgut. Atraumatic needles are preferred, particularly when suturing delicate structure such as the intestinal wall and blood vessels.

8. *Leave No Devascularized Tissue in the Wound.* This precaution applies to wounds made in the operating room as well as to accidental traumatic wounds. Devascularized tissue always encourages development of infection, particularly gas gangrene.

9. *Avoid Dead Space and Tension.* Any dead space soon becomes filled with serum in which bacteria tend to grow. Tension is very undesirable because it interferes with normal blood flow through the area and, likewise, tends to make the suture cut through the tissue, thereby encouraging wound dehiscence. At times it may be disastrous; e.g., undue tension on an intestinal suture line almost always will result in the suture cutting through, thus creating a leak.

10. *Save All Skin Possible.* No skin should be sacrificed needlessly, particularly if the patient has had an accident which has already resulted in loss of skin. Of more importance is the fact that sacrifice of skin will result in poor closure with tension and, perhaps, poor healing.

11. *Minimize the Use of Drains.* The indiscriminate use of drains, particularly those left in place for many days, is to be condemned because drains produce open wounds which encourage infection by contamination from the outside.

12. *Do Not Attempt to Substitute Chemotherapy for Good Surgery.* Chemotherapeutic agents are wonderful aids to the surgeon, but they will not act as substitutes for good surgery. Failure to observe the rules described above is apt to result in infection in spite of penicillin or sulfonamides. Moreover, once an abscess has formed, chemotherapy will not eliminate the necessity of drainage although it will minimize the spread of the infection.

are to be suspected and appropriate examinations carried out.

4. *Antisepsis.* Prevention of infection is actually best promoted primarily by mechanical cleansing, which is the most effective method of eliminating contamination. Cleansing of the skin around the wound is of preliminary importance in order to prevent further subsequent contamination therefrom. There is probably no better method of cleansing the skin than the proper gentle yet thorough use of soap and warm water. A fat solvent such as benzene or ether may be needed if a considerable amount of grease is present on the skin. The importance of antiseptics in the treatment of wounds has been greatly exaggerated, particularly because it is only a matter of a few minutes or an hour following injury until the organisms will penetrate the tissues deeply enough to prevent their destruction by the surface application of an antiseptic. Most antiseptics also inflict severe damage to the tissue cells of an open wound and in that way interfere with healing and also tend to promote infection.

5. *Anesthesia.* Some type of anesthesia is nearly always necessary in the closure of wounds. The facility of closure and débridement depends to a certain extent on the presence of good anesthesia. Choice of the anesthetic is important. Good anesthesia allows a more thorough exploration of the wound for foreign bodies, severed tendons, and nerves, and a more careful approximation of tissues. If the patient is composed and the wound small, a local anesthetic (0.5 per cent procaine) may be used; otherwise, a general anesthetic is preferable, unless the patient has eaten a significant amount of food less than two or three hours previously. A preliminary dose of morphine, hypodermically, is usually advisable regardless of whether a local or general anesthetic is used. When a general anesthetic such as ether is to be given, it is advisable to add atropine or scopolamine to the morphine in order to dry up the respiratory secretion stimulated by the anesthesia. If intracranial or intrathoracic injuries are also present, it may be imperative to use a local anesthetic even for the repair of an extensive wound because of the damage which might be inflicted on the circulation and the respiration by general anesthesia.

6. *Débridement and Closure of the Wound.* Under ideal conditions this can be carried out with full expectation of primary healing. Unfortunately, closure of the wound is not always possible. For example, *in war wounds primary closure is unsafe* (see Ch. 42). The decision as to whether a wound is 1. to be closed by primary suture, or 2. to be closed around a drain, 3. to be closed later by secondary suture, or 4. to be allowed to heal by granulation without suture depends to a large extent on the presence or likelihood of infection, which is governed by many factors. The most important factor is the *length of time which has elapsed between the injury and treatment.* In general, wounds over 24 hours old are considered too deeply invaded by bacteria to permit primary closure, although it appears that, if antibiotics (e.g., penicillin) had been given during this interval preceding repair, débridement may be done safely even though more than 24 hours may have elapsed since injury; those under 8 hours are nearly always suitable for immediate suture. In wounds between 8 and 24 hours old, the appearance and type of the wound, the probable amount of contamination, the extent of the inflammatory signs, as well as the factors mentioned below, determine the question of closure and drainage. Another important factor is the amount of traumatized tissues, dirt, and debris in the wound. In wounds treated early and effectively, however, the relation of these factors to infection and delayed healing can be eliminated in most instances by *débridement.* This consists of excision of all badly contaminated, devitalized, or jagged tissue, and the removal of all foreign bodies by careful and painstaking exploration of the injured tissue. To be properly done, débridement of the deeper portions of the wound should be done with a second set of sterile instruments.

Débridement or wound excision is the most important phase in the treatment of the wound. The primary objective is to remove all devitalized tissue and foreign bodies, with removal of minimal amount of viable clean tissue (Fig. 13). Wound excision need not be a block excision; in fact, it is advisable to excise portions of devitalized tissue at one time so that needless sacrifice of healthy tissue can be avoided. Each anatomic struc-

Until a few years ago, the true significance of loss of blood at operation or from injury was not fully appreciated. While the blood loss during débridement of a wound will rarely be serious, blood loss in accidental wounds immediately after injury may be sufficient to cause shock or death. Although not all the blood loss during optional operations, such as celiotomies, can be considered preventable, the surgeon should be aware of it, and should replace significant losses by transfusions even if no signs of shock are present. The magnitude of blood loss can readily be measured by analyzing the blood in the discarded sponges and is practically always greater than anticipated. For example, Coller and associates (15) found that the average blood loss in brain operations was 1,084 ml., in radical mastectomies, 732 ml., but in hernia operations only 74 ml. This illustrates that, when a large blood loss is expected, transfusions must be given during or immediately after operation.

When bleeding is not controlled by the usual means, i.e., by ligation of bleeding points and by pressure, one must consider the possibility of abnormal or disease processes. Occasionally such hematopoietic diseases as hemophilia (deficiency of thromboplastic substances—hereditary) and thrombocytopenic purpura (deficiency of platelets) will explain the hemorrhage. Transfusion of fresh blood is quite effective temporarily in these two conditions; platelet transfusions, which require a lot of fresh blood, are more effective temporarily than transfusions of whole blood for the latter condition. Prothrombin deficiency (caused particularly by hepatic insufficiency) should be thought of as a possible explanation, especially if the patient is jaundiced; vitamin K-like products are quite effective except when hepatic insufficiency is severe. At times the bleeding is caused by a transfusion reaction. Citrate toxicity after transfusion of many units of blood in a short time may perhaps result in bleeding, but proof is not clear; nevertheless, Allen (16) recommends giving 1 gm. of calcium gluconate (through a separate infusion set) after every second transfusion during surgery involving rapid blood loss. On rare occasions heparinoid anticoagulants or fibrinolysins explain the hemorrhage; continued transfusions appear to aggravate the bleeding in these conditions. For the former the intravenous injection of 100 mg. of protamine sulfate or 200 mg. of toluidine blue is quite effective. If hypofibrinogenemia is suspected, blood should be drawn for fibrinogen levels; a concentration below 175 mg. per cent is usually sufficiently low to justify initiation of fibrinogen therapy (17).

2. *Treatment of Shock.* If shock is present, it should be treated almost simultaneously with the control of hemorrhage; such therapeutic measures as elevating the foot of the bed and administration of physiologic saline and glucose intravenously, as well as transfusion of blood, must be instituted (see Ch. 13). However, the patient may present many of the symptoms and signs of shock, including pallor, cold sweat, vertigo, and weak pulse, but may actually be suffering merely from a "fainting attack." It will rarely be difficult to differentiate a syncope of this type from true shock if one considers the severity of injury and the physical findings. Lowering the head and inhalation of aromatic spirits of ammonia will be sufficient to combat syncope.

3. *Examination of the Wound.* This should be carried out soon after the bleeding has been controlled and shock and syncope have been treated. The wound is inspected for the possible presence of foreign bodies unless their presence can be excluded by the history. Injury to the nerves and tendons may be detected by inspection of the wound for cut ends, but a more reliable method is to examine the part of the extremity distal to the wound. *A careful sensory and motor examination must be made.* Disability in the movement of parts distal to the wound may be due to severed nerves, tendons, ligaments, or muscles. Identification of the structure damaged is determined by the location of the wound, the type of disability, and inspection of the depth of the wound. Examination should also be made for the possibility of fracture of bones (see Chapter 22). If a fracture is suspected, roentgenograms may be advisable. If the wound is located over the torso, the possibility of internal injuries must be considered; if it is present over the skull, intracranial trauma and fracture of the skull

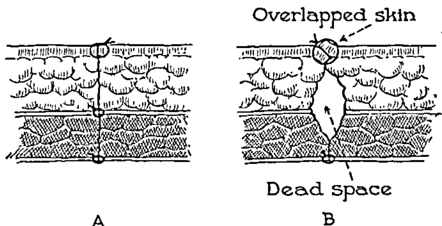

Fig. 14. Suture of a wound in layers. A, correct way to close a wound; B, incorrect way to close a wound; note the dead space in the subcutaneous tissue and the overlapping of skin edges.

trolled since blood clots encourage infection. If primary healing is excepted, nonabsorbable sutures (e.g., cotton or silk) should be used because less reaction is produced by them than by absorbable sutures (catgut); infection is therefore minimized.

After débridement is completed, the wound is closed, unless it is a war wound or is very badly contaminated with perhaps 12 to 24 hours intervening since infliction. Layer closure should be carried out if at all possible. The edges of the wound (deep and superficial) must be approximated to avoid a dead space and subsequent infection or collection of serum (Fig. 14). There must be no tension on the closing sutures; if there is, necrosis of tissue will result, and the sutures may cut through with formation of a dead space. The meticulous technic advocated by Mason (20) for wounds of the hand should be utilized in the care of all wounds (Fig. 15).

In the repair of wounds, it should be emphasized that only mesothelial surfaces will grow together. Muscle unites to muscle only by union of the fibrous tissue strands about the muscle bundles. Fatty tissue likewise unites only by union of the fibrous tissue contained in it. The best closure of a wound is obtained, therefore, when fibrous structures

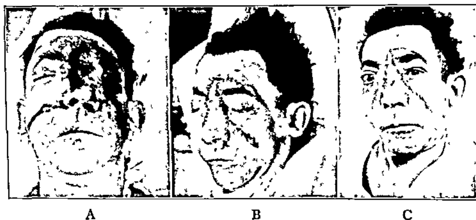

Fig. 15. Severe laceration of the face. A, photo on admission. The wound is associated with an unusual amount of trauma to the subcutaneous tissue; B, appearance of wound after débridement and closure with interrupted suture of horsehair; C, appearance of scar 10 days after accident. The mass to the right of the nose represents an enchondroma, present before the accident and not associated with the trauma. (St. Louis City Hospital.)

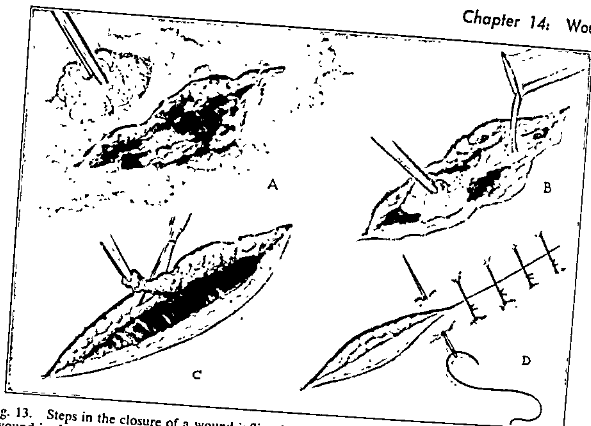

Fig. 13. Steps in the closure of a wound inflicted outside the operating room. A, the area surrounding the wound is cleansed with soap and water; B, the wound is irrigated with physiologic saline solution; C, débridement is performed, excising all traumatized and contaminated tissue. Subcutaneous interrupted sutures (usually silk) may be necessary to obtain approximation and eliminate dead space; D, the skin is closed with interrupted or continuous silk or horsehair sutures. Interrupted sutures of horsehair, nylon, or tantalum are commonly used on the face.

ture must be examined carefully and the line of excision determined by viability and presence or absence of foreign bodies. All devitalized skin should be excised. Trial excisions are carried out until a normal color and capillary bleeding are encountered. Devitalized muscle can be identified by its purple-red appearance and by its failure to contract when it is pinched. When devitalized muscle is incised, dark blood may escape; this is in contrast to bright blood which escapes in greater quantity when viable muscle is cut. Fascia is excised until a healthy surface is found. Tendons should be sacrificed only if seriously damaged or if foreign material is ground into them. Excision of nerve tissue must also be minimal. All veins in the extremities can be sacrificed, but certain arteries (e.g., popliteal) must be preserved if at all possible to prevent gangrene of the distal extremity; if such an artery is destroyed, a graft is usually advisable.

There is disagreement as to whether or not wounds should be irrigated before or after débridement. In reality, this question should be determined by certain conditions. For example, if the contamination is limited to a small area near the surface, it is better not to irrigate the wound because the deeper uncontaminated portion might then become contaminated. On the other hand if the entire wound is contaminated, irrigation is desirable. From the experimental standpoint, irrigation results in better healing in contaminated wounds, providing it is done *gently* (Peterson, 18).

The technic used during débridement must be of the Halsted (19) type, i.e., performed with gentleness and minimum trauma, and by using small ligatures and instruments. Bleeding points must be searched for and controlled by small artery forceps applied to the vessel with minimal tissue surrounding it. If the bleeding point cannot be controlled with the inclusion of a minimal amount of tissue, a transfixing suture should be inserted and a ligature tied just tight enough to stop the bleeding. Bleeding points must be con-

time when children are immunized against childhood diseases. If antitoxin is given (e.g., after infliction of a contaminated wound), it is best to allow an interval of several weeks to elapse before giving toxoid. For details of the use of tetanus antitoxin see Chapter 7.

8. *Chemotherapy*. Certain drugs may be very helpful in the prophylactic control of infection as well as in the treatment of an active infection but should never be used as a substitute for good surgery. Since a contaminated wound is apt to contain numerous organisms, more than one antibiotic is indicated in prophylaxis, as well as in treatment, in order to attain as wide a range of antibacterial action as possible. Of all agents, penicillin is perhaps the most important, largely because it is most effective against the streptococcus, which is probably the most serious of the common invaders. However, certain strains of staphylococci, which are perhaps the most common of the wound contaminants, are either resistant to penicillin or *develop resistance* to it. Moreover, penicillin is not very effective against the gram-negative organisms. Bloemers and Kempf (23) found streptomycin much more effective against *E. coli* (in peritonitis) than penicillin, and an additive though not synergistic effect when the two drugs were given together. However, aureomycin and chloromycetin are even more effective against gram-negative organisms than is streptomycin. These drugs are also strongly indicated in the presence of pyogenic organisms (especially staphylococci) which are not sensitive to penicillin. Although prophylactic chemotherapy has certain merits, Altemeier and associates (24) have very aptly summarized the disadvantages; some of these are the development of resistant strains of bacteria, production of a false sense of security on the part of the surgeon, and masking of the signs of infection.

Not all wounds are contaminated sufficiently to justify the prophylactic use of antibiotics. The factors which influence this decision are the amount of contamination, the time interval between injury and repair, the amount of damaged tissue, and the technic of repair. If administered, they should be continued for three or four days. The prophylactic dose is ordinarily less than the therapeutic dose. For detailed discussion of chemotherapy see Chapter 5.

Suture of Special Structures. When a major *nerve* has been severed it should be repaired. Before approximation, the severed ends, if jagged, should be cut across cleanly with a sharp knife. Two sutures of fine silk should be sufficient to maintain end-to-end approximation (some surgeons use fine tantalum wire as sutures). The stitch should be of the mattress type and be taken deep enough to include only the epineurium. Care should be exercised in approximating the ends in order to avoid rotation which would delay or prevent regeneration. In massive war wounds which are débrided and packed open (not closed), divided peripheral nerves are not repaired immediately, but should be approximated with a fine wire suture in order to prevent retraction, thereby facilitating second stage repair later. Details of nerve injuries may be found in Chapters 17 and 27

When *tendons* of the wrist or hand are severed, primary suture is advisable only when aseptic healing is certain. A severe infection in the presence of the repaired tendons usually results in a failure of maintenance of approximation and the development of a contracture. Years ago Koch (1931) showed that if there is a strong probability of wound infection because of a long period intervening between injury and repair, it is better to close the wound and perform the tenorrhaphy at a later date. Koch emphasized the fact that infection of the wound following repair of a tendon surrounded by a sheath is much more apt to result in a permanent contracture (because of the spread of the infection throughout the sheath) than when the sheath is absent. He concluded further that, as a rule, if more than four hours have elapsed since injury to a palmar tendon, it is wiser to close the wound and perform the tenorrhaphy after the wound has healed. The decision as to repair of the tendons must be made by the surgeon, depending upon the type of wound, because in many instances, if the wound has been made by a clean, sharp object and properly cared for, repair of tendons may be successful when six to eight hours have elapsed following injury, particularly since the ad-

can be approximated. A drain is rarely indicated unless hemostasis has been unsatisfactory or a dead space could not be obliterated; in such a case, it may be removed in 24 hours. For closing the skin, interrupted or continuous sutures of fine cotton or silk are usually used, but, on the face, where a minimal scar is desired, some type of suture with a surface which is impermeable to moisture (e.g., horsehair, dermal, and nylon) will be superior, because less reaction is produced in the tissue about the suture. Interrupted sutures are usually used on the face. Details of suture material, drains, and infections are discussed elsewhere in this chapter.

If closure of the wound is not possible because of destruction of skin and subcutaneous tissue, a flap should be created to fill up the deficit, or a skin graft should be applied. In severely contaminated wounds immediate closure may be undesirable, but, after four or five days, secondary closure may be possible. Antibiotics are not routinely used, but, under such circumstances, they are indicated.

The principles just discussed in the treatment of accidental wounds can be applied to a great extent to *wounds made in the operating room*, the most important of which are *abdominal incisions*. Incisions in the abdominal wall should be oblique or transverse (21) whenever possible because postoperative strain is less likely to lead to disruption. Most surgeons use interrupted, nonabsorbable sutures to close the fascia of abdominal wounds on the assumption that less infection, wound disruption, and postoperative hernias will ensue. The skin adjacent to the wound should be covered with sterile drapes. The wound itself is by no means sterile, as has been demonstrated by numerous workers who have obtained positive cultures in practically 100 per cent of clean abdominal wounds made in the operating rooms. This is explained by the fact that such factors as the skin, the air, and improper masking are serious sources of contamination. During operation, all tissues including the intestine must be kept moist with sponges, because drying of tissue results in its death. Most surgeons who advocate nonabsorbable sutures prefer not to bury catgut in the same wound on the assumption that this increases the possibility of infection. Stay sutures are rarely necessary when abdominal wounds are closed with silk or cotton. To combat the development of infection in abdominal wounds contaminated by spillage during such procedures as colonic resections, gentle irrigation with physiologic saline may be instituted at the end of the operation. Antibiotics are not placed in the wound when contamination is sustained, but their use systemically may be very effective in lowering the incidence and severity of infection.

7. *Tetanus Antitoxin* (*A.T.S.*). This need not be given if the wound is small, superficial, and inflicted by a clean sharp object. In deep punctured wounds antitoxin is especially indicated, unless the wound has been caused by an instrument such as a clean, smooth needle. In localities where tetanus is prevalent because of such factors as extensive use of manure as fertilizer, administration of tetanus antitoxin as a routine may be indicated even in small wounds. It should always be given when the wound is extensive or contaminated with dirt and foreign bodies. A dose of at least 1,500 units, subcutaneously or intramuscularly, should be given. Some authorities (Spaeth) recommend much larger prophylactic doses. In gunshot wounds or in massive wounds inflicted in barnyards or in the streets, a dose of 5,000 to 10,000 units should be given. Since the immunity conferred by the administration of a dose of tetanus antitoxin *lasts no longer than 10 to 14 days*, it will be necessary to *repeat the prophylactic dose* if operative procedures about the original wound are contemplated more than two weeks after administration of tetanus antitoxin. In view of the marked prophylactic value of penicillin procaine in the development of tetanus experimentally (Taylor and Novak, 22), it is probably desirable to give this agent in large doses to patients having heavily contaminated wounds. If there is massive destruction of tissue with excessive contamination, a prophylactic dose of gas bacillus antitoxin should be given as well as tetanus antitoxin. Individuals (especially children) who are subject to frequent injury should be immunized actively with tetanus toxoid. This is now common practice at the

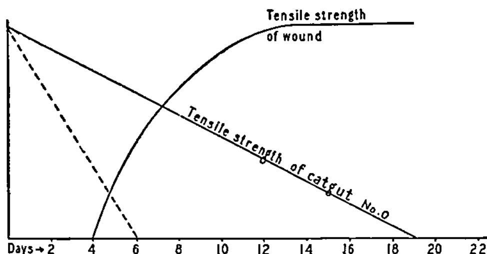

Fig. 16. Relation of decreasing tensile strength of catgut to increasing tensile strength of wound (healing under aseptic conditions). The broken line illustrates the rapid loss in tensile strength of even large catgut (No. 2, plain) in an infected wound. (Modified from Howes and Harvey. New England J. Med.)

a permanent foreign body and, in grossly infected wounds, does not lead to persistent drainage, as would be the case with nonabsorbable sutures. The *disadvantages* of catgut are that it can be sterilized less readily than silk and that a reaction in the tissue with a tendency toward development of infection follows its use; in a study of 2,360 inguinal herniotomies, Shambaugh noted that the incidence of suppuration was twice as great in those closed with catgut as it was in those closed with silk. Moreover, in the presence of infection its tensile strength decreases rapidly even though chromicized gut is used (Fig. 17). In the presence of infection, catgut delays healing. Jenkins and associates (26) have shown that many brands of catgut are preserved in chemicals which are extremely irritating to tissues. Unless the preservative is known to be harmless, all cat-

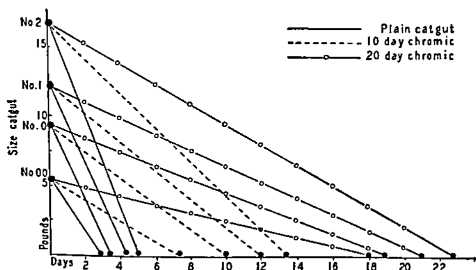

Fig. 17. Decrease in tensile strength of various sizes of catgut buried in a noninfected wound. Note that regardless of size, plain catgut (indicated by solid line) loses its tensile strength within five days, whereas, 20-day chromic catgut (indicated by line with circle) loses its tensile strength only after 18 days even in the finest (00) size. (From Howes and Harvey. New England J. Med.)

vent of penicillin. The slow rate of healing of injured tendons, which is probably dependent upon inadequate blood supply, demands secure fixation and approximation of the cut ends over a period of seven to twelve days. Therefore fine silk is the suture of choice since catgut may be absorbed too soon. Details of the treatment of severed tendons may be found in Chapter 17.

Any wound sustained over a *joint* should be closely inspected for possible laceration of the joint capsule. If an opening is found, it is imperative that the joint be inspected for foreign bodies and dirt, and, if present, these must be removed. Removal of debris is facilitated by irrigation with a solution such as physiologic saline. The wound in the joint capsule should then be closed by interrupted sutures of fine silk. The rest of the wound is closed in the routine fashion. It should be inspected daily, and the patient's temperature should be observed closely for the possible occurrence of infection within the joint. The presence or absence of pain about the joint is usually helpful in determining whether or not an infection has occurred. It is imperative to discover the infection as soon as it occurs so that the joint may be reopened and the chance of destruction of the cartilage minimized (see Chapter 24).

Sutures. There are numerous varieties of suture material in use at the present time. Many of them are merely substitutes for each other without obvious advantages or disadvantages. However, on certain occasions one type of suture will be superior, whereas on other occasions a distinctly different type of suture will have obvious advantages.

Types of Suture Material. Sutures are classified as absorbable and nonabsorbable. The latter type is not affected by the digestive action of body fluids and leukocytes and remains indefinitely, unless cast off or removed. Nonabsorbable sutures most commonly are of silk, but linen, nylon, cotton, dacron, orlon, silver wire, silkworm gut, and varieties of vegetable fiber (dermal) are also used under special conditions. Silk may be used in a variety of sizes from the finest, split strands to thick, braided cords. The advantages of silk lie in the fact that it does not lose its tensile strength, except to a slight degree, and holds the approximated structures together almost indefinitely. Silk provokes a minimum of tissue reaction in the absence of infection, and healing therefore is accompanied by very little scar tissue. Silk, moreover, has such intrinsic tensile strength that very fine strands are adequate to hold most structures in place. The *disadvantage of silk* is confined to its action in the presence of infection, for under such conditions it acts as a foreign body and, as already mentioned, will prevent healing until it is discharged. However, wounds closed with interrupted silk will tolerate contamination better than wounds closed with catgut, although if the wound does become infected some of the silk sutures will be extruded. Since the onset of World War II cotton is displacing silk to a great extent, although its tensile strength is not as constant as silk; it invokes perhaps even less reaction in tissues than does silk (Meade and Ochsner, 25). Practically all the other remarks made about silk apply also to cotton. Other nonabsorbable suture materials such as horsehair, linen, metal clips, dermal (vegetable fiber), and nylon are available but are used largely in the skin. In recent years two or three types of fine, pliable metallic sutures made of stainless steel and tantalum have been introduced. They are, of course, nonabsorbable, strong, and well-tolerated by tissues even in the presence of infection.

Absorbable sutures are those which are digested by the tissue juices and leukocytes and replaced by scar. Catgut is the most common representative of absorbable suture, but kangaroo tendon is sometimes used. Catgut is of animal origin, being prepared from the submucosa or fibrous layer of the terminal ileum of sheep. It is prepared in a variety of sizes, from the finest, No. 00000, to No. 2 or larger, which is quite stout. Slow absorbability is achieved by treating the material with various chemicals, usually potassium bichromate. Potassium mercuric iodide, tannic acid, and other chemicals are likewise used to decrease the absorbability. One *advantage* of catgut is that, as it is absorbed, scar tissue becomes deposited which binds the approximated structures together (Fig. 16). Since it is absorbed, it does not act as

the other hand, it is probably also true that if this same care in technic is utilized, fine catgut will give fairly satisfactory results. In other words, the "philosophy" of silk technic (including gentle handling of tissue, careful application of hemostats, and use of fine sutures), as originally developed by Halsted (19), *should be mastered by all surgeons and* will no doubt be responsible for much better results than a technic of careless and rough handling of tissue, which is bound to be detrimental to healing of wounds. The reason a great many competent surgeons still use catgut and are not inclined to change to silk lies in the fact that they are using silk "philosophy" in the use of catgut, and are, therefore, obtaining such good results that they see no reason to change. Unfortunately, this is not true in all instances.

Drains. Although drains are distinctly contraindicated when aseptic healing is expected, there are occasions when the closure of the wound around a drain is advisable. The use of drains in the repair of accidental (i.e., grossly contaminated) wounds is confined chiefly to two types: 1. in wounds where hemostasis could not be satisfactorily attained (under such circumstances the drain is removed in 12 to 24 hours when all bleeding has stopped), and 2. in wounds where dead space could not be effectively eliminated. Opinions differ considerably as to whether or not a drain should be left in wounds which are closed eight hours or more after the injury. Some surgeons are of the opinion that, if infection develops, the presence of a drain will help to keep the process localized and to produce fewer systemic or local manifestations. This is no doubt true, but it is also true that on numerous occasions the drain will act as a foreign body and aid in the development of an infection, whereas the wound would not have become infected if it had been closed without drainage. This is particularly true of wounds closed with catgut, since a catgut suture encourages the development of infection more than does a nonabsorbable suture. The argument cannot be settled by a dogmatic statement because it is impossible to predict which wound would or would not become infected. The use of drains in abscesses is discussed elsewhere.

A small strip of rubber dam is superior to almost any other type of drain and in most instances should be anchored with a suture to *prevent losing the drain* in the depth of the wound. The loss of the drain in the wound may also be prevented by attaching a safety pin to that portion outside the wound or by using such a large piece that it is impossible for the entire drain to be lost in the wound. When draining sma'l wounds a wick made of doubling several strands of catgut or silkworm gut may be adequate. When a penetrating and very extensive wound needs drainage, a large drain will, of course, be needed. Tubular drains made of soft rubber (Penrose) are splendid for this purpose. Rubber dam may be rolled up to the size desired and is very satisfactory because it is soft and pliable and, therefore, causes no pressure necrosis, which can be a serious complication, indeed, if the tissue involved is intestine.

In most instances, a drain left in a wound at time of closure may be removed in 24 or 48 hours. If a definite infection develops, it may be advisable to keep a drain in the wound for several days. The length of time is dependent upon such factors as the severity of the infection, the size of the cavity, and the efficiency of the drainage. Although gauze wicks or packs are very useful in stopping hemorrhage from the edges of the wound, they do not serve as drains because the mesh rapidly becomes plugged with fibrin. Gauze wicks or packs should be removed in 12 to 18 hours and a rubber drain should be inserted if drainage is desired for a longer period of time.

The use of large rubber tubing for drainage of wounds, as so often recommended, is in reality to be condemned, except for drainage of large cavities (e.g., empyema), because of the pressure necrosis which they are apt to produce.

Postoperative Care. On many occasions healing by *primary or secondary union is de*termined largely, if not entirely, by the postoperative care of the wound. If the wound is large, this treatment can best be carried out in a hospital. Hospitalization is likewise strongly indicated when a large vessel has

gut must be washed *thoroughly* before being used.

Application and Choice of Sutures. When a wound is superficial and the subcutaneous tissue is not gaping, closure of the skin with a continuous or interrupted suture of fine cotton or silk will suffice. Black silk may have a slight advantage over white because in most types of tissues it can be seen more readily. For approximation of the skin, other nonabsorbable material may be used, including cotton, linen, metal clips, metal sutures, nylon, and dermal sutures. If the wound is on the face, interrupted sutures of fine horsehair should be used since this type of suture encourages healing with the least amount of scar tissue. Because of the need for good cosmetic results in wounds of the face or scalp, these sutures may be removed on the second to the fourth day. Most of the nonabsorbable sutures mentioned above may also be used as subcutaneous sutures and, in fact, are preferred over catgut. The only precautions are that fine sizes should be used and no sutures should be placed immediately under the skin because, when they are placed too close to the skin, they tend to work out of the wound.

If an operation must be conducted through a frankly infected field, catgut is the suture of choice because it is absorbed and, therefore, does not tend to produce persistent drainage through foreign body action, as might be the case with nonabsorbable sutures.

Formerly, stay sutures were placed through all layers of the abdominal wall, in addition to the regular layer closure; however, there is fairly good evidence that they not only fail to prevent *wound disruption* but actually are harmful because of the ischemia produced at the point of constriction by the suture. Accordingly, stay sutures are rarely used for the closure of abdominal wounds (Fig. 18). Disruption of an abdominal wound is rarely caused by breakage of the sutures but usually develops because they cut through tissue. Wound disruption commonly occurs in patients with such maladies as jaundice and inoperable carcinoma, especially when the patients are undernourished. A severe strain on the suture line, caused by persistent cough, hiccup or retching, is also a common or important factor in *disruption*, which is discussed on page 281.

The advantages of silk over catgut in clean wounds have already been discussed in this chapter and are particularly valued and demonstrable in thyroidectomies and herniotomies. However, it is important to emphasize again that a much more careful technic is necessary if silk is to be used without the serious complication of the development of infection with persistent sinus formation. On

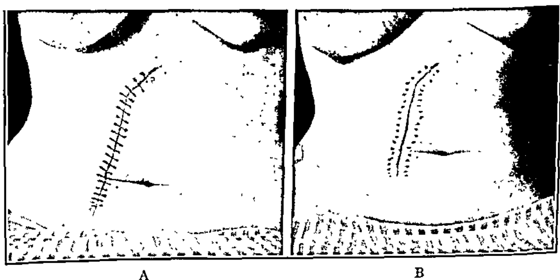

Fig. 18. Abdominal incision (laparotomy) healing per primam. A, five days after closure of skin with continuous cotton suture. B, ten days after operation. The sutures were removed on the seventh postoperative day.

tant to immobilize the extremity, including the joint, when the wound is located over the extensor surface of a joint. If the wound involves the joint capsule, complete immobilization is indicated until such time when the possibility of infection has been eliminated (four to eight days).

Removal of Sutures. The time for the removal of sutures depends in general on the rapidity of the fibroblastic reaction. There is a latent period of approximately four days before significant tensile strength develops. It is only after 10 to 14 days that this process reaches a level. Skin sutures, however, may be removed much earlier than this, i.e., five to seven days after injury, depending upon the location of the wound. In an area as vascular as the scalp, and in regions where little movement is present, sutures can be removed at the end of 48 hours, especially if subcutaneous interrupted stitches have been applied. On the face, which is likewise quite vascular, wounds also heal rapidly; some of the sutures (perhaps every other one) may be removed on the second day and the rest on the third day or fourth day, depending upon the condition of the wound. If they are left in place longer, the amount of scar formation is increased. Skin sutures should not be removed from a wound in a dependent position, such as the leg, earlier than the eighth postoperative day unless it is a very superficial wound. The dependent position and the movements associated with walking delay healing, and the wound edges are apt to separate if stitches are removed earlier than the eighth day. However, when the wound is not in a dependent position, ambulation appears to accelerate healing.

Symptomatic Treatment. Under this heading may be included numerous miscellaneous therapeutic measures, the chief ones of which are medicinal. On many occasions it may be advisable to prescribe a sedative (aspirin, codeine) for pain or discomfort, especially if the patient is nervous and easily excitable. If a local anesthetic (procaine) has been used there may be considerable burning for an hour or two while the effect of the anesthetic is wearing off. This may be relieved by a hot water bottle.

WOUND DEHISCENCE

Separation of wound edges may be due to many causes, which may be summarized as traumatic or nutritional. Patients who have persistent coughing (Fig. 19), vomiting, or hiccup after operation have a high incidence of disruption, particularly if the patients are jaundiced or have inoperable carcinoma. Age is also a factor, as indicated by the clinical study conducted by Marsh and associates (27); these investigators found that the average age of patients having dehiscence was 56 years compared to an average age of 48 in patients whose wounds did not disrupt. Dehiscence of abdominal wounds is most common between the eighth and twelfth days. The first evidence of disruption of an abdominal wound is often a sudden discharge of sanguinous fluid. Sudden development of anorexia in patients who have started to eat following celiotomy is often the first sign of a partial wound separation. Emergency closure is indicated in all patients with complete disruption and in most patients with partial separation. The edges of disrupted wounds reveal surprisingly little reaction, but when they are closed with through-and-through sutures, they heal remarkably well. In fact, Savlov and Dunphy (28) have shown experimentally that wounds which have disrupted and have been resutured actually heal more rapidly than those healing under normal circumstances.

CRUSHED WOUNDS

Obviously, crushed wounds of varying severity may be produced with or without destruction of the skin. One of the most frequent types of crushed wounds encountered at the present time is that inflicted by the electric wringer on the upper extremity (usually in children). However, fractures are rarely produced by this type of injury. The enormous amount of pressure exerted by the wringers produces a varying amount of permanent damage to the skin, subcutaneous tissue, and muscles (Fig. 20). Most of the damage to the skin is inflicted usually on the forearm at the point where the wringer stops (or perhaps spins). Not infrequently, the skin is damaged so much that ultimately (after a few days) it becomes gangrenous.

been severed and secondary hemorrhage is likely.

TYPES OF DRESSING. When the wound has been closed without drainage, nothing more than a sterile, dry, gauze dressing need be applied. If the wound is deep, or hemorrhage likely, it is usually advisable to apply a firm dressing so as to minimize the possibility of bleeding and the formation of a hematoma. Dry dressings have an obvious advantage over others in that the secretions which escape from the wound edges are rapidly absorbed by the gauze and bacteria which may be present in the secretion are killed or inhibited by drying. A dry dressing, likewise, allows the edges of the wound to adhere fairly firmly in 36 to 48 hours with the formation of a crust which seals the wound, thereby minimizing the possibility of infection from the exterior. Silver foil, partly because of its antiseptic qualities, is an excellent dressing and is used extensively over craniotomy wounds. Ointments are disadvantageous because they prevent drying and the formation of the protective crust, thereby encouraging the development of secondary infection. However, if the gauze sticks to the wound it will be necessary to apply a small amount of petrolatum or bland ointment to prevent pain and injury to the regenerating epithelium on the edge of the wound at subsequent dressings.

Gauze dressings may be anchored by adhesive or a bandage. A bandage is apt to be more comfortable and will assist in absorbing wound secretions but cannot be applied conveniently on the torso. On certain occasions when it is necessary to apply a small dressing (as on the scalp) the dressing may be anchored by collodion or liquid adhesive, which must be applied only on the edges of the dressing so as not to seal over the wound edge. It should be stated that some surgeons do not use dressings on clean wounds. However, the justification of this procedure is not yet proved.

TECHNIC OF DRESSINGS. In clean wounds dressings need not be changed until time for removal of sutures, unless evidence of infection or other complications develop. For example, the dressings on laparotomy wounds need not be changed until the sixth or seventh day, when the skin sutures are removed. This is a precaution taken to minimize secondary infection. However, if fever, pain, or leukocytosis develop, indicating the possible presence of infection, the dressing may be changed at any time. The dresser should wear a mask and pair of gloves; the latter need not be sterile but should be washed in soap and water between cases after contamination. At least two hours should elapse after sweeping floors before dressings are changed. If an indurated, reddened area is found suggesting the presence of an abscess, drainage will be indicated. Usually all that need be done is to remove a few sutures to allow spreading of the wound and evacuation of the pus. The opening in the wound should be enlarged so that practically the entire extent of the abscess is opened for drainage. Soft rubber drains can be inserted but are usually not necessary. Hot, wet dressings encourage drainage and healing. The treatment of infection is discussed later in this chapter.

If there is question as to the possible formation of a hematoma, or dead space, the dressings may be removed at any time indicated. With sterile gloves, or palpation over a sterile towel, the indurated area in the wound may be detected and the cavity drained. Drainage can be accomplished by insertion of an instrument through the suture line into the cavity, after first painting the area with a mild tincture of iodine or other nonirritating antiseptic to prevent contamination into the depths of the wound. Evacuation of the hematoma or dead space is usually sufficient to take care of the complication, but, if large, the cavity may be drained for 24 to 48 hours with a soft rubber drain. A pressure dressing may be very helpful.

IMMOBILIZATION. One of the most important features in the postoperative treatment of wounds is *immobilization of the injured part*. Any movements which allow the wound edges to become detached and traumatized will, of course, delay healing and may encourage the development of infection. If the wound is on the upper extremity, a sling may be sufficient to obtain this immobilization. If the wound is on the lower extremity, it may be necessary to confine the patient to bed for a few days. For obvious reasons, *it is impor-*

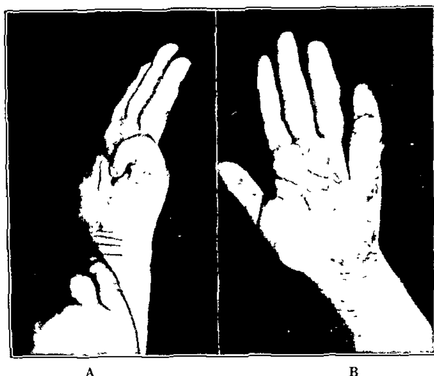

Fig. 20. Crushed wound producing flexion contracture of finger. A, two months after crushing of hand by an electric wringer; no open wound was sustained. B, the scar was excised, the finger released, and the resultant defect repaired by a "flap" skin graft removed from the inguinal region. (St. Louis City Hospital.)

of the bones obviously adds to the severity of any crushing injury. Treatment of such crushing injuries should be undertaken with extreme conservatism. Years ago, before the aseptic era, amputation was frequently necessary because of the likelihood of severe infection. The various aspects of crushed extremities as related to amputation are discussed in Chapter 13.

INFECTED WOUNDS

All open wounds sustained by accidents are contaminated; most of them will become infected unless treated adequately by methods already described in this chapter. Even the majority of wounds created in the operating room for elective procedures are contaminated by one or more of the various mechanisms described in Chapter 4; some of these are so badly contaminated that infection develops later after closure. In general the development of infection depends on three factors: (1) the amount of contamination, (2) the virulence of the organism, and (3) the resistance of the patient, i.e., as related to immunologic factors. A substance recently isolated from blood serum by Pillemer and associates (29) and given the name *properdin* promises to be a very potent factor in the resistance of the body to infection. It is a protein (euglobulin) comprising not more than 0.03 per cent of the total serum protein. The properdin system, consisting of properdin, complement, and magnesium has been identified as a natural defense mechanism of blood (Benson and associates, 30). "It kills certain bacteria, neutralizes some viruses, and lyses certain abnormal erythrocytes"; it functions without a specific antibody. Benson and associates report further that a depression in the properdin level is noted in pulmonary complications, paralytic ileus, peritonitis, gastrointestinal bleeding, and surface wound infections but does not persist beyond the duration of the disease process. No changes were noted following anesthesia, operative or accidental trauma, removal of the adrenal glands, or removal of the spleen. More study of this substance will be required to determine how

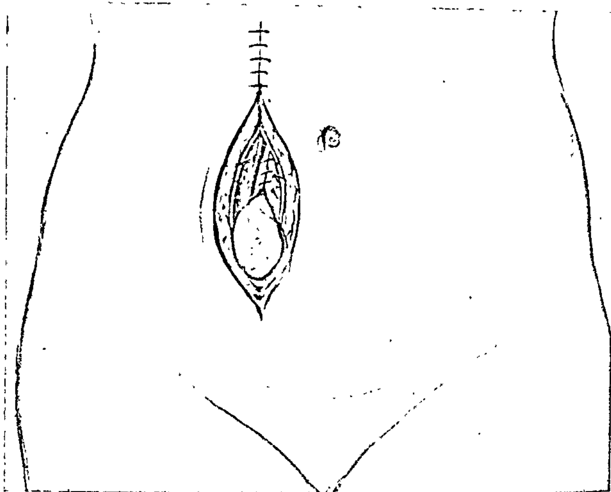

Fig. 19. Dehiscence of abdominal wound. This patient, age 65, had a carcinoma of the pancreas and had been jaundiced for six weeks. Because the tumor was advanced, only a cholecystojejunostomy was done. The patient developed postoperative atelectasis with persistent coughing. On the eighth day the dressing suddenly became stained with serous fluid; inspection of the wound revealed a small loop of ileum protruding. Closure with through-and-through silk sutures was carried out.

Rarely is the defect large enough to demand skin graft. A variable amount of swelling, produced by edema and hemorrhage, develops shortly after the injury. Such injuries are usually very painful. A surprisingly large amount of disability (fingers and hands) is associated with the injury. Not infrequently, there will be sufficient scar deposited in or about the muscles and tendons to produce a permanent contracture. Prompt incision of the fascia overlying the damaged muscle will prevent contracture if swelling is marked.

Occasionally, crushing injuries of the extremities as sustained in railroad accidents, for example, may be of sufficient magnitude to demand amputation. Laceration and tearing of the skin and deep tissue usually exist. Large vessels may be torn, resulting in severe hemorrhage which may be internal or external, depending upon whether or not the skin is broken. Crush injuries are often accompanied by severe shock which is not always helped by transfusions of blood or plasma. Formerly it was assumed that the loss of serum and blood was the major factor in the production of shock. At present considerable evidence has been adduced that a special entity called *crush syndrome* may follow crushing injury. A toxin, presumably of bacterial origin, is produced in the crushed muscle; when this toxin is absorbed, it gives rise to serious manifestations of shock and to renal damage later. The extravasation of fluid, and hemorrhage from smaller vessels may be sufficient to compress the larger vessels and produce gangrene per se. Fracture

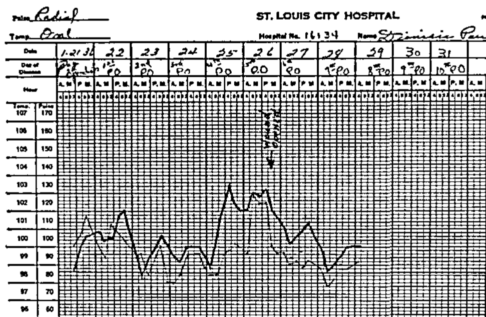

Chart 1. Postoperative wound infection in a 25-year-old man following a herniotomy. Note the fall in temperature following the opening of the wound. The organisms cultured from the pus were streptococci and staphylococci. The infection was traced to a respiratory infection in one of the operating room personnel. Recovery was uneventful.

from slipping into the depth of the wound. If the entire wound is infected and the symptoms are fulminating, it will be advisable to remove all the sutures and open the wound in its entire extent for adequate drainage. Such radical treatment is frequently necessary when the causative organism is a virulent streptococcus. On most occasions, drainage, as mentioned above, may be instituted without an anesthetic simply by separating the wound edges. Counter incisions of course require an anesthetic, local or general.

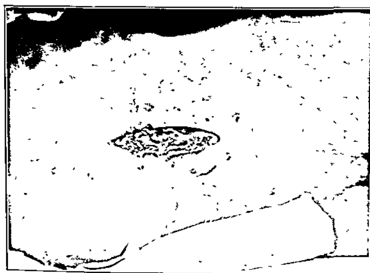

Fig. 21. Postoperative wound infection. A few days after laparotomy the entire wound became swollen, reddened, and tender and was therefore opened for drainage by removal of all skin sutures. Healing is now (two weeks after operation) taking place by the process of granulation.

this information can be utilized in the treatment of infection.

Mucoproteins appear to aid the body in its fight against infection or to increase the efficiency of antibiotics. For example, Howes and Armitage (31) noted that when 0.1 per cent mucoproteins were combined with antibiotics in the treatment of experimental wounds four hours after infliction, the development of infection was only 10 per cent as compared to 50 per cent infection if antibiotics were used alone.

The mechanisms of contamination in infected wounds have already been discussed but are summarized briefly here. In accidental wounds, contamination at the time of injury is obvious. In wounds made in the operating room, contamination takes place most commonly from the mouth of the personnel. Coughing, sneezing, and forceful breathing will force air through the average mask so suddenly that filtration of the air by the mask is ineffective. Contamination of gloves by touching nonsterile objects is common with inexperienced personnel. Less commonly, faulty sterilization may be the cause of contamination. The air in the operating room always contains a certain number of bacteria; the actual number of bacteria is related to the ventilation and number of people working in the operating room. The danger of infection of wounds in the operating room through inadequate ventilation of the operating room has been emphasized by Shooter and associates (32).

Clinical Manifestations. The classical manifestations of wound infection are redness, pain, tenderness, swelling, and local heat. In addition an induration is present at the site of infection. Fever develops relatively early in all acute infections. On some occasions, lymphangitis evidenced by a red streak leading from the wound (or a point nearby) will be present. Lymphadenopathy involving the nodes to which the wound is draining is present in practically all patients with wound infection. Leukocytosis is common. In the late stage of infection when pus accumulates, fluctuation will be present unless the infection is deep. Numerous systemic manifestations including headache, malaise, anorexia, weakness, and backache, may be present. With streptococcus infections, the above manifestations may develop in 24 to 48 hours; in staphylococcus infections, the manifestations develop more slowly, at times not becoming prominent for four to six days. Other organisms commonly found in wounds by culture are *Escherichia coli, Proteus vulgaris*, and *Pseudomonas aeruginosa* (*Bacillus pyocyaneus*). Detailed enumeration and description of organisms producing wound infection may be found in Chapter 6.

As the infection progresses, granulation tissue develops as a mechanism of protection and healing. It is moderately impervious to penetration by bacteria, and, if a layer of granulation tissue develops around the infected area, the infection with its accompanying manifestations will be limited, to some extent at least.

Treatment. The *importance of rest* of the affected part in the treatment of infected wounds should again be emphasized. If the wound is on an upper extremity, a sling may furnish sufficient immobilization; if on a lower extremity, bed rest may be required. Treatment varies considerably, depending upon the type and severity of infection. In the absence of suppuration, drainage is unnecessary, but, if there is any question about the presence of pus, a blunt instrument may safely be inserted between the edges of the wound under sterile precautions to determine whether or not pus is present. If a few drops of turbid fluid or pus are found, the insertion of a small rubber drain will do no harm and may prevent spreading of infection into the adjacent tissue. When a wound becomes infected (though not requiring removal of skin sutures), the sutures must be left in longer than the regulation time of five or six days because of the delayed healing and consequent danger of separation of the wound edges.

If an abscess develops in the wound, it should of course be opened as soon as detected (Chart 1). Two or three sutures may be removed, the wound spread, and the pus evacuated (Fig. 21). If the cavity is not large, such an opening should be adequate, especially if a rubber dam drain is inserted. As mentioned previously, such drains must be anchored in some way to prevent them

cated. However, because of the development of resistant organisms by chemotherapy, there is a growing tendency to use prophylactic therapy less and less. It should be emphasized that prophylactic antibiotic therapy must not be given to patients having such uncontaminated wounds as herniorrhaphy, appendectomy for unperforated appendicitis, and cholecystectomy.

When incision into the intestinal tract is contemplated—as, for example, colectomy for carcinoma—considerable contamination of the peritoneal cavity and wound may take place. Accordingly, the use of antibiotics to reduce the number of bacteria in the lumen of the intestine is justifiable, although a few surgeons may not agree. If intestinal antisepsis is sought, neomycin is about the most effective agent. It is often combined with oxytetracycline (Terramycin) or bacitracin. The latter agent is particularly effective against streptococci and clostridia, whereas neomycin is particularly effective against *Escherichia coli* and proteus; accordingly these agents act in a synergistic manner. Neither is absorbed from the intestinal tract; systemic reactions are therefore extremely uncommon. Some surgeons are of the opinion that Sulfathalidine is less apt to result in development of resistant strains of bacteria.

When antibiotics are given for *treatment of active infection* the offending organism should be identified. Accordingly, a culture should be obtained as soon as the infection is discovered, but a broad-spectrum antibiotic should be given until sensitivity tests on the organism are completed. The sensitivity tests should be conducted on five or six important antibiotics, such as penicillin, streptomycin, tetracyclin, chloramphenicol (chloromycetin), and erythromycin. If the organism is resistant to these, it should be tested with still other antibiotics. Although penicillin is very effective against the streptococci, numerous strains of staphylococci are becoming resistant to it. In general, there is not a very significant tendency for organisms to become resistant to chloramphenicol and erythromycin; accordingly, these antibiotics are becoming quite useful in the treatment of active infection. Erythromycin is particularly effective against most of the stains of staphylococci which are resistant to penicillin; it is not very effective against gram-negative organisms. Polymyxin is perhaps more effective against the pseudomonas (pyocyaneus) organisms than any of the other agents in use at the present time; however, nephrotoxicity is occasionally encountered with systemic use of this agent.

Some antibiotics act synergistically whereas others are antagonistic. For example, Jawetz (34) has found that synergism often exists between two of the bactericidal group (penicillin, streptomycin, polymyxin, neomycin, and bacitracin) and between the bacteriostatic group (chlortetracycline, oxytetracycline, and chloramphenicol). However, he noted that antagonism often develops when one of the former group is given with one of the latter. Details of chemotherapy may be found in Chapter 5.

Although the antibiotic and chemotherapeutic agents discussed above are very effective in the treatment of infections, the sulfonamides must not be forgotten. Often they are effective when used with one of the agents just discussed, or they may even be effective when used alone (see also Chapter 5).

In *summarizing* the treatment of infected wounds, the importance of obtaining early and adequate drainage of the wound should be emphasized. If the infection is mild, a simple separation of the wound edges with the insertion of a small rubber drain may be sufficient. If an abscess cavity has formed, the wound must be opened adequately, and, if necessary, counter incisions may be made so that there are no undrained undermining pockets. Rest of the affected part is extremely important in preventing the invasion of new tissue by infection. Cleansing of the infected wound by daily dressings is known from experience to encourage healthy granulations and healing; however, unless proper aseptic technic and gentleness are maintained during change of dressings, more harm than good may result. Aseptic technic in dressing is, of course, essential in order to prevent secondary infection, especially during the time before a wall of granulation tissue has formed in the wound (five to six days). Antibiotics are very effective in the

Except in mild infections, hot wet dressings are beneficial and usually advisable for 24 to 48 hours. If the wound is extensive and considerable necrosis of tissue is present, Carrel tubes may be inserted and the wound irrigated with a solution of penicillin (250 to 500 units per ml.). After the infection has subsided and the cavity has been obliterated, the edges of the wound, if small, may be approximated by means of adhesive; it may be advisable to do a secondary suture.

If the wound is large, *secondary closure* will be indicated to shorten the period of convalescence and repair. Areas of granulation tissue no wider than 1 or 2 cm. will be covered fairly satisfactorily by epithelial regeneration. If epithelium is allowed to cover areas wider than this, it will be thin and covering a dense layer of scar; thus, it will not be very resistant to the irritation to which skin is normally subjected. Epithelium will not grow down into a cavity; the cavity must first be filled with granulation tissue. If the granulating wound is wider than 2 or 3 cm., secondary closure or skin graft to the area will be indicated. Secondary closure cannot be done successfully until all necrotic tissue has separated and the granulation tissue has a pink healthy color. Closure can be accomplished more successfully if it is done before the depression at the site of wound separation has filled in. At times it may be necessary to undermine the skin and subcutaneous tissue to obtain good approximation, but this is undesirable because the protective layer of granulation tissue is thus broken and bacteria from the granulating surface are allowed to invade the fresh tissue opened by the undercutting incisions. In the average infected wound, secondary closure must be delayed 6 to 12 days after the incision has been opened to drain the infection. However, when fresh wounds are left open because of severe contamination during accidental infliction, secondary closure may at times be carried out successfully in two or three days. Such wounds should be packed with dry gauze, and heavy chemotherapy should be instituted to prepare them for such early closure. Local application of the enzymes streptokinase and streptodornase, as introduced by Tillett and associates (33), may be helpful in shortening the period of preparation of the wound.

Dressings on infected wounds should be changed every day to prevent pooling of the purulent exudate. Dressings should consist of dry gauze or wet dressings. As the granulation tissue develops, it is usually desirable to cover the wound with a strip of fine mesh gauze which will prevent granulation tissue from growing through the interstices of the gauze.

Skin grafts can be applied when all necrotic tissue has disappeared and the granulation tissue has a healthy pink color. It is usually desirable to wait until the depression created by separation of the wound edges has filled in with granulation tissue. Since full-thickness grafts will not take on granulation tissue, Thiersch grafts are the grafts of choice; they are superior to pinch grafts because final healing is slower after application of pinch grafts.

Chemotherapy in the treatment of wounds may be prophylactic or given for active infection. Each is important, but the principles utilized in the two methods are quite different.

Prophylactic chemotherapy is designed to prevent development of infection following contamination. It must be realized that all accidental wounds are contaminated; so also are abdominal wounds in operations during which the intestinal tract is entered. Under these circumstances the indications for chemotherapy are by no means clear-cut. In accidental wounds, prophylactic therapy will not be indicated if the wound is relatively clean, particularly if treatment is carried out within a few hours following injury; however, it will be indicated in all patients with grossly contaminated wounds. Since the contaminating organisms in accidental wounds are extremely variable, it is desirable to give an antibiotic or combination of antibiotics havings a wide spectrum of activity. A combination of penicillin (1,000,000 units per day) and streptomycin (2 gm. per day) meets this need about as effectively as any other agent or agents. This treatment should be continued for five or six days. In patients having operations on the intestinal tract, the same antibiotic therapy may be indi-

section except when sharp dissection becomes dangerous. Scissors may be used for blunt dissection but should not be used to cut tissues. Artery forceps should be placed on the bleeding point, avoiding large bites. Retraction must be gentle, and other precautions must be taken, as previously described in this chapter. A few years ago when the diathermy or electrosurgical knife was introduced, it was thought that less trauma would be inflicted on the wound because very few ligatures were required. However, even the slight charring of the skin induced by the electric knife resulted in damage to tissue which, as was shown by Ellis (35), delayed healing to such an extent that primary healing was obtained in only 60 per cent of instances versus 97 per cent following incision by a sharp scalpel.

4. **Lack of Immobility.** Lack of rest for the effected part is very detrimental to healing and, in the case of freshly closed wounds, may result in infection or hemorrhage. Perhaps more frequently, however, it delays healing by breaking down the newly regenerated tissue, which is very friable and nonresistant to stresses when only a day or two old. Even though rapid healing calls for immobility of the injured part, the patient himself should be ambulated unless contraindicated for reasons discussed elsewhere.

5. **Mechanical and Chemical Trauma.** The constant irritation by portions of clothing or appliances likewise interferes with healing to the extent that removal of sutures in the routine time (five to six days) may allow the wound edges to fall apart, even though infection is absent or not demonstrable. Obviously, any severe trauma, such as a blow inflicted over the wound, may destroy the repair which has taken place since the injury by disrupting the adhesion of the edges and sides of the wound. The application of ointments containing irritating chemicals (particularly phenol) will also interfere with healing. One of the most frequent causes of delayed healing of an abdominal wound, even to the point of actual rupture, is the development of a persistent cough during the first days of convalescence. Active measures must be undertaken to eradicate cough, retching, vomiting, hiccups, and excessive movements of the patient to prevent delayed healing. However, tight abdominal binders are undesirable because they interfere with respiration and may produce pulmonary complications.

6. **Foreign Body.** Any wound tolerates the presence of a foreign body poorly. Although certain objects (e.g., Lane plates, braided silk sutures, and other coarse fixative material) sometimes remain innocuous in aseptic wounds, they should be used only when necessary because of the tendency to convert a minimal contamination into a severe infection with the development of a *persistent sinus* (Fig. 23). Obviously, the more "dirt" that is imbedded with the foreign body, the more likely is the possibility of development of infection. On the other hand, a clean object, such as a piece of glass from a broken tumbler, may be buried in a wound, which

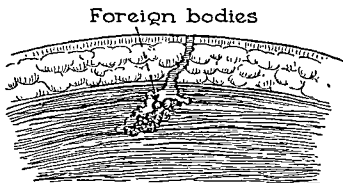

Fig. 23. Infection and sinus formation resulting from retained foreign body in the wound. The wound was carelessly closed without proper débridement and removal of foreign bodies, which are still embedded in the subcutaneous tissue. Healing is impaired, in fact prevented, by the foreign bodies and consequent suppuration.

invasive stage of infections, particularly those produced by the coccus organisms. However, they are not a substitute for incision and drainage of an abscess.

CAUSES OF DELAYED HEALING

1. **Infection.** Of the many instigating factors, the most important cause of delayed union, at least from the standpoint of frequency, is infection. In the presence of infection the incised tissues of the wound fail to adhere to each other and pus accumulates between them. This failure of union is usually more marked in the subcutaneous tissue than in the skin itself. The presence of an infection in a wound, even though it is adequately drained, may delay solid healing with complete closure from the average time of about 10 days to several weeks.

Occasionally a chronic infection, such as blastomycosis, actinomycosis, tularemia, and tuberculosis, is implanted into the wound at the time of injury and results in the formation of a chronic ulcer or sinus. The various peculiarities of these infections should lead to a correct diagnosis. Although many such infections are very resistant to treatment, they are fortunately not common.

Practically all the conditions listed below as factors in the causation of delayed healing are, likewise, important because of the tendency to encourage the development of infection. In many instances a wound becoming infected and healing by secondary intention would have healed per primam if that factor had been eradicated.

2. **Incorrect Closure.** If the subcutaneous tissue of the wound is closed inadequately so that a dead space is formed, fluid will accumulate within it and will remain for many days before it is absorbed and the cavity is filled with granulation tissue. If the skin edges are overlapped during approximation, they will separate and expose subcutaneous tissue when the sutures are removed (Fig. 14).

Not infrequently a hematoma will form within the depth of the wound because of failure to ligate all bleeding points at time of closure of the wound. Occasionally, a vessel which is cut or torn at the time of injury is not bleeding during closure of the wound, but the clot in its lumen becomes dislodged, and hemorrhage ensues after closure. This is prone to occur when a low blood pressure develops during the operation and returns to normal after closure of the wound.

3. **Excessive Trauma During Operation.** As stated previously, careful surgical technic aids asepsis. Careless technic, including rough handling of tissue and excessive trauma, results in delayed healing, not only because of the increased tendency to infection, but also because of the excessive amount of necrotic tissue produced (see Fig. 22).

Incisions should be made with a sharp scalpel, which should likewise be used in dis-

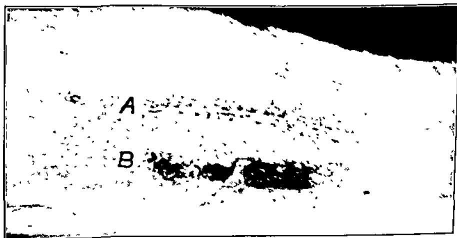

Fig. 22. Photograph illustrating the value of careful operative technic. Both incisions were made on the animal's abdomen seven days previously. Wound A was made and closed with careful technic whereas in wound B the tissues were handled roughly, with crushing of tissue, and so forth.

of rats, at least the ones guilty of attacking the sleeping human being, are infected with the spirochete (*Spirillum minus*) which is responsible for rat-bite fever (see Ch. 7).

Snake bites are dreaded, perhaps, more than the bites of any other animal, but fortunately, of the various kinds of snakes found in North America, only four are poisonous. The rattlesnake, copperhead, cottonmouth moccasin, and coral snake comprise this group. At the present time, several reputable pharmaceutical companies make an antivenene which contains antitoxin for the toxin contained in the venom of the first three snakes mentioned above and, if given in time (up to 8 or 10 hours) and in large quantities, may prevent a fatal outcome. Unfortunately, antivenene is rarely available at the time of injury, and it is necessary to resort to other measures while this is being procured. If the bite is inflicted by one of the four snakes mentioned above and on an extremity, it is advisable to apply a tourniquet which is tight enough to obstruct the lymphatics—part of the venous flow—but which *must not* block the arterial supply. Cross incisions are then made with a sharp knife through the fang marks. Suction is very effective in draining toxin out of the incised area, providing the incisions have been made adequately. The best method to apply suction is to use a regular cupping apparatus; if not available, one may be made by taking a large rubber bulb and inserting the end of a small funnel into the open end of the bulb. In absence of such apparatus, suction may be achieved by the mouth although the resultant infection is a serious disadvantage. There need be no fear of being poisoned by the absorption of venom through the mouth or intestinal tract, since the venom is destroyed by the digestive ferments. Absolute rest of the patient is essential. One of the most serious mistakes that can be made is to give the patient large doses of alcohol, since the depressant effect of the alcohol accentuates the depressant effect of the venom on the medullary centers and thereby hastens death. The seriousness of snake bites is considerably exaggerated since not over 15 to 18 per cent of untreated rattlesnake bites in adults are fatal. The bite of the cobra, encountered in the Eastern Hemisphere, is by far the most fatal of all snake bites. About 40 per cent of

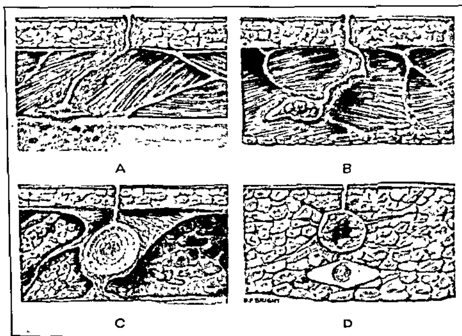

Fig. 24. Types of sinuses. A, sinus maintained by a foreign body (sequestrum); B, insufficient drainage of an abscess retards healing and may encourage spread of the infection; C, sinus communicating with a tuberculous lymph node; D, sinus connected with a pilonidal (epithelial lined) cyst which tends to become infected even before primary rupture of the sinus; strictly, this is a fistula.

will heal without the subsequent production of any difficulty except pain and local tenderness over the object. Some foreign bodies which are supposedly inert may interfere considerably with healing even though present in small quantities. Talcum powder, which was used years ago to powder hands and gloves, is an example of such an irritant; the resultant tissue reaction may give rise to granulomas and scar formation. Corn starch preparations, specially treated to maintain lubricating qualities after autoclaving, appear to be satisfactory substitutes.

7. **Impaired Circulation.** An example of the deleterious effect of impaired circulation on the healing of a wound is encountered when a patient is allowed to walk around as usual with a wound on one of the lower extremities. This delayed healing may be manifested by a slight amount of redness and edema, due presumably to the inadequate circulation created by the dependent position. Removal of sutures under eight days in such instances may result in separation of the wound edges. The sluggish healing of wounds in the lower extremities of patients with varicose veins, arteriosclerosis, and other vascular diseases may be explained on the basis of impaired circulation. On rare occasions, bandages, casts, or splints may be applied so tightly as to prevent healing because of impaired circulation resulting therefrom.

8. **Malignancy.** A wound inflicted in malignant tissue will very seldom heal. This situation will rarely be encountered in wounds sustained in accidents but is a frequent cause of difficulties in the operative treatment of malignant disease. For example, if the anastomosis following the excision of a carcinoma of the intestine is performed through malignant tissue, there will very likely be a leak at that point because of lack of healing. Such a complication is, of course, very serious because it usually leads to general peritonitis.

9. **Malnutrition.** Wounds sustained by patients suffering from a severe grade of malnutrition and dehydration usually heal very slowly. Severe anemia may delay healing. More important in the proper healing of [illegible] protein nutrition, as emphasized years ago by Clark (10), and Howes (11), and others. Ano portant cause of delayed healing an disruption lies in a low vitamin C blo Proof of this relationship was first by Lanman and Ingalls (8), who sh animal experiments (guinea pigs) th the vitamin C content in the blood the scorbutic level, delayed heali wound disruption were common. T tionship of tissue and blood pro wound healing and various surgical cations has been discussed in detail din and Gimbel (12).

10. **Miscellaneous Causes of Healing.** There are numerous local which may be responsible for lack ing, especially when the wound is loc one of the lower extremities. On ra sions, delayed healing will be caused temic diseases such as syphilis and culosis.

WOUNDS INFLICTED BY ANIMALS AND INSECTS

Dogs and cats are responsible for the wounds inflicted by animals. The bility of contraction of rabies from th other animals is discussed in Cha Moreover, there is a strong possibility development of local pyogenic infecti cause of the myriads of pathogenic isms constantly present in the mou such animals and because of the pene nature of the wound made by the Wounds caused by the bite of a cat are more prone to become infected than caused by a dog, but neither are as li result in infection as a bite inflicted man teeth (see p. 350). If the wo superficial (e.g., a cat scratch) an within a few minutes following the i thorough cleansing with soap and wa the application of an antiseptic such as cent aqueous solution of iodine (U may be very helpful in preventing the opment of infection. A sterile dressing of course, serve as a protection and p secondary infection.

Rat bites are not uncommon and are commonly sustained at night while th tient is asleep. A surprisingly large nu

sess the qualities of permanency or chronicity. 3. There are several *chronic infections,* including especially tuberculosis and actinomycosis, which form sinuses resulting from the rupture or incision of abscesses which fail to heal. 4. A sinus is often due to the presence of *epithelial cells* lining the track. These cells secrete more or less constantly and prevent healing and closure of the sinus. A common example is the draining wound in the neck caused by a persistent thyroglossal duct. Another example is a pilonidal cyst which so commonly opens to the exterior and fails to heal.

Any *treatment* which aims to eliminate a sinus depends, of course, upon the etiologic factor. This must be determined if possible. Injection of the track with a radiopaque substance (iodized oil) followed by a roentgenogram often reveals the extent and relationships of the sinus. Examination by the roentgen ray will also aid in this differentiation if a radiopaque foreign body is present. Gentle probing of superficial sinuses occasionally reveals the presence of a foreign body. After removal of foreign bodies, sinuses usually close within a few days. A secreting epithelial lining must be completely removed by excision or destroyed by chemical cauterization, preferably the former. A preliminary injection of the sinus track with methylene blue will so visualize its ramifications as to make complete excision easier. If inadequate drainage is the cause of the sinus, a thorough incision should be performed. If tuberculosis or actinomycosis is the etiologic factor, local treatment will usually be facilitated if the entire local process can be removed.

FISTULA

A fistula is an abnormal communication between epithelial- or endothelial-lined surfaces (usually hollow viscera) or a communication between a viscus and the exterior. They may be produced in several different ways.

1. Occasionally the communication may

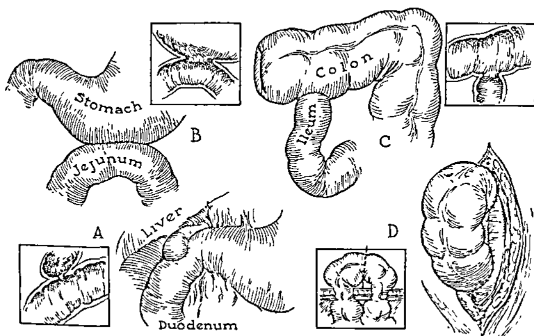

Fig. 26. Common types of intestinal fistula produced by operative means. A, cholecystoduodenostomy, performed usually for carcinoma of the pancreas or inoperable carcinoma of the ampulla of Vater; B, gastrojejunostomy, utilized in stenosis of the pylorus or duodenum; C, ileocolostomy, commonly performed in resection of the proximal colon for carcinoma; D, double-barreled colostomy, as performed to correct obstruction in inoperable carcinoma of the rectum, or in the Lockhart-Mummery type of resection of the rectum for carcinoma. On the second or third day the sigmoid is cut across, as shown by the dotted line in the insert.

Fig. 25. Sinus of groin. The patient was a four-year-old boy who stepped on a sharp object while playing; the wound healed (above), but two months later lymph nodes in the groin suppurated; after incision of this abscess, a sinus (below) developed and persisted for a year. Excision resulted in a cure. Microscopic section revealed chronic inflammation (not tuberculosis). Culture was negative. This chronicity is rather unusual, but chronic sinuses develop occasionally, particularly when the organism is microaerophilic.

people bitten by the cobra will die unless treatment is given instantly and adequately. ACTH and cortisone are quite effective in the treatment of snake bites. Hydrocortisone given intravenously will act more rapidly.

There are numerous insects whose bites are poisonous, but very few, indeed, are fatal. The most common of the poisonous bites are those inflicted by the black widow spider and the scorpion. The condition produced by the bite of poisonous spiders is called arachnoidism. The black widow spider is probably the most poisonous of all the members of the Arachnida class of insects. It is about 1 cm. in size and is recognized by a red area shaped like an hourglass on its abdomen. Important to the surgeon is the fact that the bite of a black widow spider may be soon followed by severe abdominal pain; examination may reveal a hard "boardlike" abdomen which simulates that observed in perforated peptic ulcer. There is, however, little associated tenderness, and, within a few hours, the signs and symptoms gradually disappear although distention may be present and persist for several days. The bite is associated with a fatality of less than 1 per cent (Kirby-Smith, 36).

SINUS

A sinus is a tract extending from the surface of the body into the deeper tissues, which frequently becomes the site of chronic discharge or suppuration. The superficial part of the lesion may appear to be a simple ulcer, but the history and examination will reveal its true nature. There are four main factors (Fig. 24) in the production of a sinus: 1. *Foreign bodies* such as metal, wood, unabsorbable sutures, necrotic bone (sequestrum), and fecaliths, in the presence of an infection, may lead to a sinus which may be permanent unless the foreign body is removed. 2. Perhaps the most common sinus encountered results from *insufficient drainage* of an ordinary pyogenic infection. The cause of the insufficient drainage may be inadequate incision of an abscess, tortuosity of the drainage tract, the presence of a collar-button abscess, lack of a dependent opening, or chronically infected lymph nodes (Fig. 25). When an ordinary abscess heals there is usually an interval of a few days when a discharging inflammatory tract is present after the walls of the cavity have approximated. Theoretically this should be called a sinus, but obviously it does not pos-

the patient does not first succumb to peritonitis caused by the leak in the suture line.

The *treatment* of fistula depends upon its location and cause. If the communication has followed some type of infectious process, excision of the fistulous track and closure of the opening in the viscus will usually effect a cure. A fistulous communication between two loops of intestine may be cured by dissection of the walls from each other, excision of inflammatory edges, and closure of the openings. Resection of the affected loops followed by an anastomosis may be necessary. The edges of the opening in the intestine must be inverted since union will occur only when the peritoneal surfaces are approximated. A fistula produced by malignant tumors cannot be cured by closure with sutures, but it may be eliminated if the growth can be completely excised and the resultant defect repaired with complete obliteration of dead space at the site of excision.

As already stated, most fecal fistulas, with the exception of those high in the intestinal tract, will heal spontaneously unless there is an obstruction distal to the fistula. If such an obstruction is present, it will obviously have to be corrected by operative means before the fistula will close. If the fistula persists because of attachment of the intestinal mucosa to the skin, an operation consisting of division of the union between mucosa and skin with inversion of the intestinal mucosa should result in a cure. Occasionally, such a repair will produce so much narrowing of the intestinal lumen that either obstruction or a recurrence of the fistula will result. On such occasions, resection of the defect, with an anastomosis between the two loops (proximal and distal) of intestine is indicated.

As will be noted in the above paragraph, the suffix "*ostomy*" is commonly utilized to signify a fistulous communication between different organs of the body (especially intraabdominal). The term implies the opening of an organ without closure and establishment of communication with another organ or the exterior. The suffix "*otomy*," however, implies the opening of the organ or viscus and closure without establishment of a fistulous tract. When the suffix "*ectomy*" is used in connection with an organ or tissue, excision of that organ or tissue is implied.

be *congenital*, that is, result from a defect in fetal development. Rectovaginal, rectovesical, and rectal fistulas are often associated with an imperforate anus.

2. *Postoperative fistulas* may be divided into two types. In the first group (*a*) the fistula is produced intentionally (Fig. 26), connecting one viscus with another for functional reasons, e.g., cholecystogastrostomy, ileocolostomy, gastroenterostomy. In a second group of cases (*b*) the fistula opens to the outside through accidental or intentional means, e.g., urinary fistula, biliary fistula. Pancreatic fistula and duodenal fistula likewise occur and develop most commonly following operations on the duodenum. A biliary fistula which persists is usually due to an obstruction distal to the opening. In a *fecal fistula* (Fig. 27) the intestinal content is diverted to the outside; it is frequently performed intentionally, e.g., colostomy, during a resection of a carcinoma of the rectum. When a fecal fistula results accidentally, it usually occurs because of a rupture of an intestinal suture line, which in most instances is caused by an obstruction distal to the

operative site. (Frequently, such : of intestinal contents produces a fata tonitis before a fecal fistula develops most occasions, fistulas which devel the absence of obstruction will close taneously; they may drain for months, ever. If the fistula is located high ii intestine, it will usually not heal spon ously; furthermore, it may result in th gestion of the skin or the walls of the wo

THERMAL, CHEMICAL, AND ELECTRIC TRAUMA

A number of different kinds of trauma are considered in this chapter, all due to the effects of abnormal heat or cold, chemicals, electricity, and ionizing radiation. Abnormal cold causes freezing; high environment temperature causes heat stroke and heat exhaustion. The latter produce systemic effects but are not usually associated with any local lesion. Electric currents may burn or coagulate the skin and deeper tissues directly, may kill without obvious skin damage, or may cause flame burns by setting clothing on fire. Atomic explosions lead to burns and other systemic damage.

THERMAL BURNS

The skin and underlying structures may be burned by flames, by contact with hot water or other hot liquids, by hot metallic objects, by the sun, by contact with radiation from other hot bodies, by steam, by electricity, or by friction. Burns caused by hot liquids or steam are frequently called *scalds*. *Flash burns* are due to sudden exposure to the heated air of flame from an explosion, including that of an atomic bomb.

Pathology of Burns. Tissue changes caused by thermal injury vary with the duration and intensity of the exposure, and the particular part of the body involved. These tissue changes often lead to systemic effects which will be described under clinical manifestations.

Classification of the skin lesion in burns has always proved somewhat difficult and even now is sometimes confusing. This is due partly to an attempt to use too rigid criteria and partly to the fact that only with the passage of time can the true extent and depth of the necrosis be accurately estimated. In the following discussion, the extent (as measured by the depth and area of the burn) and the kind of damage will be used as the two primary groups for classification.

The Extent of the Burn. The local skin lesion may vary (*a*) as to depth, and (*b*) as to the area involved.

1. The *depth of the burn* is traditionally classified into first, second, and third degree. *In third-degree burns, the necrotic skin* which finally sloughs off extends through the entire derma (see Fig. 9 on p. 307). The first- and second-degree burns always heal spontaneously, whereas the third-degree burns, unless of a small area, always require a skin graft. An excellent study of this subject is that of Converse and Robb-Smith (1) who have classified the depth of burns into four types: 1. *epidermal,* in which erythema is followed by desquamation but without blistering; 2. *dermal,* in which blistering and superficial destruction of the derma is accompanied by edema into and under the skin, transudation into the blisters and through the bed of broken blisters, and hyperemia in the tissues under the burn; 3. *deep dermal,* in which there is destruction of

fixing tissues and vessels in controlling hemorrhage, J.A.M.A., 60:1119, 1913.

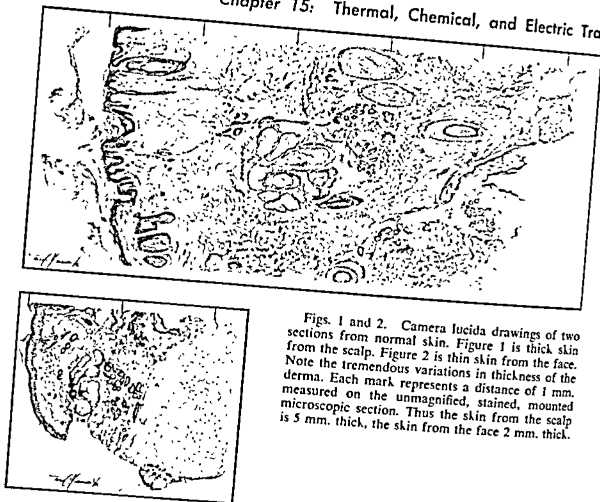

Fig. 3. Flash burn. Photograph taken on the tenth day following an explosion from a gasoline stove. Note the outline of the brassière which protected the underlying skin. The burned areas were practically all part thickness and complete healing can already be seen over the right side. The necrotic crust over other areas came away shortly afterward, leaving a healed base. The distal portion of the left upper arm was merely "tanned" without necrosis, as shown by the appearance of normal skin over a small area from which the superficial keratin layer could be readily removed.

Many of the burns following the atomic explosion in Hiroshima also showed the outline of clothing, indicating the protection offered from many flash burns by even light wearing apparel.

example, a fatal result may be expected in an extensive burn assumed to be all of third degree, whereas cure will follow because only a small portion was actually of third degree, as shown by the relatively small amount of skin grafting subsequently required. On the other hand, a less extensive and supposedly superficial burn may eventually prove fatal because it involved all thicknesses of the skin, as shown by sloughing later.

2. The *area of the burned skin* has an important influence upon the degree and severity of the systemic effects and especially on mortality. In general, serious reaction follows only in burns larger than 10 per cent of the surface area, the severity increasing directly with the percentage. However, the systemic effects also vary with the depth of the burn, its kind, and the age and general vigor of the patient. The aged, and very often children, are very much more vulnerable than young adults. The area of the burned skin is customarily expressed as a percentage of the total skin surface. This information, including an estimation of the depth of the burn, is essential not only for the care of the patient but for scientific study of burns in general. Helpful charts for measuring and recording the burned area in terms of percentage have been published by Lund and Browder (3) and are reproduced in Figure 4, which also shows the differences in various body areas at different ages.

The Kind of Damage. Entirely apart from depth and area, the thermal agent may produce either edema and swelling, or actual necrosis, or both. Moreover, the necrosis may be of the moist type or may be dry and hard. Moreover, these three kinds of tissue damage—edema, moist necrosis, and dry necrosis—may all be present in different parts of the same burn. In general, the necrosis tends to be moist in the periphery of the burn, hard and dry in its center. Exposure to very high temperature for a short time tends to cause a dry burn or eschar. Exposure to a lower temperature for a more prolonged time causes a necrosis with edema. Thus, flame burns are more apt to produce dry necrosis, hot-water and oil burns, moist necrosis. Such differences in the kind of skin damage are important not only in terms of eventual healing but particularly in the production of systemic manifestations, which are least apt to occur with dry necrosis and most apt to occur when there is considerable edema and/or moist necrosis. The latter is particularly likely to produce "toxic" manifestations due to the absorption of bacterial

Figs. 1 and 2. Camera lucida drawings of two sections from normal skin. Figure 1 is thick skin from the scalp. Figure 2 is thin skin from the face. Note the tremendous variations in thickness of the derma. Each mark represents a distance of 1 mm. measured on the unmagnified, stained, mounted microscopic section. Thus the skin from the scalp is 5 mm. thick, the skin from the face 2 mm. thick.

the deep layers of the derma, sparing the deepest epithelial elements such as hair follicles and the coils of sweat and sebaceous glands; 4. *deep,* in which the destruction of the derma includes all epithelial elements into and/or beyond clear fat of subcutaneous areolar tissue. Although a deep burn of this classification looks like a deep dermal burn, it is fundamentally different because spontaneous healing can occur in the latter, but not in the former, from remaining epithelial islands representing remaining portions of the hair follicles or sweat glands. *Mixed* burns, a separate group, are those in which small areas of deep dermal are interspersed with small areas of dermal burns.

It cannot be emphasized too strongly that an accurate estimation of the depth of the burn cannot always be made at the initial examination. Time must elapse until healing is well under way or, at least, until the overlying necrotic skin has been sloughed. Recent experimental studies on animals with radioactive phosphorus show that the depth of the burn may be estimated early, perhaps within hours of the accident (2). Some preliminary information may be gathered from the part of the body involved and the kind of thermal injury. As to the former, the thickness of the derma is important and differs widely in various parts of the body (Figs. 1 and 2). Moreover, the circulation of the blood also plays an important part by carrying away heat imposed by the thermal agent. For example, although the skin of the face is thin and presumably would be damaged more deeply by a given burn, the cooling effect of its excellent blood supply actually protects the tissues so that deep lesions are relatively uncommon in this part of the body. As to the kind of burn, a much deeper burn nearly always follows when the clothes catch fire than is true of a hot-water or a flash burn. If not ignited, clothing will usually protect against flash burns (Fig. 3).

Mistakes in prognosis are commonly due to erroneous estimates of the depth of the burn made at the initial examination. For

indicate "toxemia" as *shown by high fever,* increasing coma, irrational behavior, and irregular respirations. Later in the course of the burn, if severe infection supervenes, the *usual systemic manifestations* of suppuration will follow.

Anuria may occur after extensive burns. Even when uremia is not progressive the patient shows some depression of the sensorium, a diminution in the urinary output, and an increase in the nonprotein nitrogen of the blood. When occurring shortly after the burn, these manifestations may, however, be due to a decrease in blood volume and are often relieved by replacement therapy.

3. The *local lesions,* as already described, vary widely. *The history is of some value in that burns due to the actual flame, especially* when the clothes have caught fire, are nearly always deeper than scalds and produce a dry necrosis which (unless charred), on cursory *inspection,* may look like blanched skin. On palpation, however, such doubt is dispelled, for the coagulated tissue is insensitive and hard.

4. *Laboratory studies* should be started on admission and continued at frequent intervals until healing. A systematic approach is essential. On admission, a urine specimen is obtained and examined as routine with special reference to hemoglobinuria and cellular casts. Because knowledge of renal activity is essential (especially the prompt detection of oliguria or anuria), the severely burned patient should always be provided

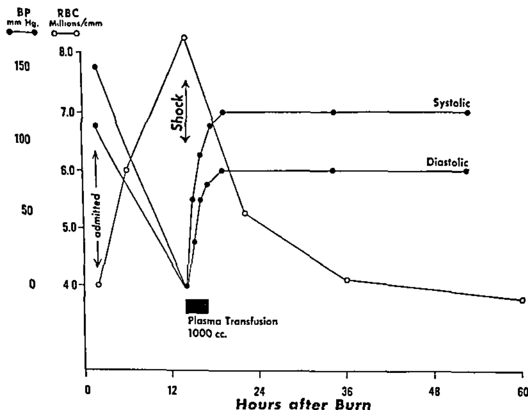

FIG. 5. Surgical shock and hemoconcentration in a severe burn. The patient, a seven-year-old boy, entered the hospital almost at once after sustaining a flame burn involving 30 per cent of the body surface. Note that on admission the red cell count was normal and that the blood pressure was slightly high. The patient's general condition was good and he took food and fluid well. Within 12 hours, however, typical shock developed with cold extremities, rapid pulse, and unmeasurable blood pressure. The red cell count increased synchronously. A rapid and large plasma transfusion (30 ml. per kg. of body weight) was followed by dramatic clinical improvement and, as shown in the chart, a prompt restoration of blood pressure and correction of hemoconcentration. Healing was eventually complete but required skin grafting. (From Elman, Merry, Beguesse, and Tisdale, Surg., Gynec. & Obst., 4.)

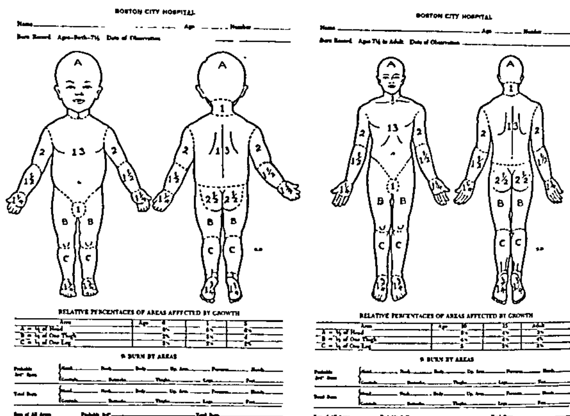

Fig. 4. Charts for measuring extent (area) of burn. Note that the area of the skin burned is expressed as a percentage of the total surface area. The numbers recorded are those of the feet, upper extremity, neck, and torso because these are the same at all ages. Note that the head, thighs, and legs (indicated by letters A, B, and C respectively) vary with age; during growth the surface of the head grows proportionately smaller, that of the thigh and leg larger. (From Lund, C. C., and Browder, N. C. Surg, Gynec. & Obst.)

toxins which have invaded. Thus, the kind of skin damage may greatly influence the likelihood of systemic disease.

Burns involving the respiratory tract are discussed later.

Clinical Manifestations. As might be expected, the clinical picture in a severe burn varies greatly due to the great variations in the extent and type of the local lesion, as well as in the age and general condition of the patient. The various manifestations are arbitrarily divided into the following five groups.

1. The *subjective symptoms* may be relatively few, even in severe burns. *Pain* is always intense at the time a flame or hot-water burn is sustained but usually disappears rapidly. Sunburn, however, is usually painful later and not initially. Ordinarily, the burned patient arriving at the hospital complains merely of discomfort, even though he may be apprehensive. Undoubtedly the memory of the intense pain plays an important part in these subjective manifestations. A second symptom of importance is intense *thirst*. Except when vomiting occurs, thirst is readily satisfied by drinking fluids which, however, should contain 0.5 to 0.8 per cent sodium chloride and bicarbonate. Pure water ingested in large amounts may lead to salt deficiency (water intoxication). Chilliness, even in warm weather, is a frequent complaint, but always disappears after the burned area is covered by the application of a dressing or is exposed to warm air.

2. The *systemic manifestations*, even with extensive burns, may be surprisingly few on admission to the hospital shortly after the burn is sustained. While the blood pressure may be reduced, it is frequently unchanged; the pulse may also be normal. The temperature, however, is often elevated. Within a few hours, however, particularly when there is extensive extravasation of fluid, the blood pressure may fall and the patient may exhibit all the signs of surgical shock. In other patients, the systemic manifestations seem to

weeks and months because of the poor general condition of the patient; yet, with the passage of time the general condition may deteriorate rather than improve. In many instances, this deterioration is based on extreme malnutrition due to a combination of anorexia and increased nitrogen loss from the excessive tissue protein destruction. These manifestations may be prevented to a great extent by special and early attention to nutritional intake as discussed under treatment.

Treatment. The fundamental principles of treatment are: 1. to lower initial mortality; 2. to avoid infection; and 3. to shorten disability and promote healing (4). Systemic therapy, because it is designed to lower mortality, rightly demands rigid priority.

1. *Systemic treatment* aims to combat shock and toxemia by replacing lost fluids and correcting other biochemical changes. Highest priority is given to restoring the blood volume to normal. Pain must be controlled when present, although most patients are free of it at the time they enter the hospital for treatment. The routine use of large doses of morphine is therefore unnecessary and indeed undesirable, because it depresses respirations, which is dangerous in the presence of pulmonary complications. If morphine is necessary, it should not be given subcutaneously or intramuscularly to patients in shock, but injected intravenously.

Prevention of deficits will undoubtedly reduce early mortality in most severe burns. The basis of this therapy is accurate replacement of losses which, especially when they occur in extensive edematous areas, consist essentially of physiologic saline solution plus some plasma protein and red cells. In addition, insensible losses of pure water are also increased, because of (*a*) fever and increased respiration, and (*b*) increased vapor loss through the burned rather than through the intact skin (Lieberman, 5). An important feature is to meet the needs of thirst, not by water alone, which may indeed reproduce signs of water intoxication, but by a dilute solution containing 0.4 per cent sodium chloride and 0.1 per cent bicarbonate. Most patients willingly drink this instead of water, especially if it is chilled.

Intravenous injections are not always necessary inasmuch as many burned patients will take an adequate amount of the right kind of fluids and food by mouth. However, in the presence of shock and hemoconcentration, especially in a patient who vomits, the intravenous channel must be used. In a carefully studied group. Markley and associates (6) found that 55 per cent of all patients with burns involving 10 per cent or more of the body surface were able to take all foods orally. About 40 per cent received fluids both orally and intravenously, and the rest by vein exclusively. However, up to 50 per cent of all patients had vomiting and/or diarrhea.

Intravenous infusions are indicated when blood or plasma is needed. The type of intravenous fluids to be given has aroused some dispute, but the best guide is a knowledge of the kind of fluid lost, so that true replacement therapy can be practiced. It is likely that the proponents of saline on the one hand and plasma or blood on the other are both correct in that the fluid lost in burns is a protein-containing extracellular fluid. Thus, the proper replacement would consist of physiologic saline, plus plasma and blood, the amount of each dependent upon the amount of insensible water loss, the extent of inflammatory edema, the degree of hemoconcentration, and the urgency of restoration of blood volume as shown by the signs of shock. Additional guides are the clinical response to therapy, the restoration of urinary output, and the estimates of fluid balance. Such a therapeutic approach actually is simpler and more likely to meet individual needs than is a strict adherence to rigid formulas. Rarely with pulmonary edema following respiratory tract burns (see p. 309) intravenous treatment may be contraindicated.

The principles expressed by Evans (7) may serve as guides to replacement therapy. For example, he has stated that if the burn includes more than 25 per cent of the body surface, about as much blood should be given as whole blood plasma or plasma substitute. For the first 24-hour period he suggests plasma, plasma substitute, or blood in quantities equal to 1 ml. per kilogram times the percentage of body surface burned; an equal

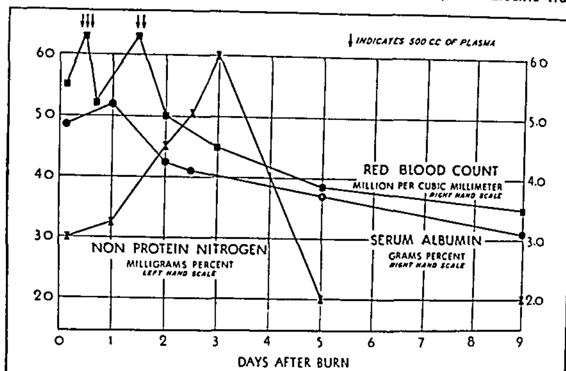

Fig. 6. Blood changes in a severe burn. The patient was a 45-year-old female whose clothes caught fire; she sustained a third-degree burn on about 40 per cent of the body. Note the complete correction of hemoconcentration following transfusion of 2,500 ml. of plasma and the fall below normal, in spite of this, of the serum albumin. Note also the rise and fall of the nonprotein nitrogen.

with an indwelling catheter in the bladder and all urine collected, measured, and examined. The red count and hematocrit or hemoglobin determination are of special importance because they show the onset and progress of hemoconcentration and thus give an indirect measure of decreases in blood volume (Fig. 5). Red cell counts as high as eight million per cubic millimeter have been found in severe cases. One or more of these examinations should be done every six hours for two days and at frequent intervals thereafter. The white cell count will nearly always show a leukocytosis, usually up to twenty thousand or more. The eosinophils disappear rapidly within a few hours, a manifestation of the so-called "stress reaction."

Blood chemical measurements include the nonprotein nitrogen content and serum and fractional proteins (Fig. 6). Acidosis, as shown by a low carbon dioxide combining power of the plasma, is not infrequent, particularly in severe burns. Such a finding represents an important feature of the systemic manifestations. A low plasma sodium either is due to the ingestion of pure water or is a part of the presumed change in cell permeability secondary to stress. With oliguria and anuria, the usual changes of renal insufficiency are found. Hypoproteinemia is apt to occur after several days and to progress if the nutritional intake is inadequate. Although hemoconcentration is frequent within 12 hours, anemia may occur after a few days and sometimes may be pronounced. Anemia is probably due to an actual destruction of red cells, to hemolysis, or to a depression in the normal hemopoietic function of the bone marrow.

5. *Later manifestations* are serious, but fortunately occur only in fairly extensive full-thickness burns in which there is a complete loss of skin. To a certain extent, many of these later manifestations are due to extensive suppuration, and the clinical manifestations are similar to those produced by infection from any other cause. Sooner or later, however, with adequate local treatment, necrotic tissue separates and the patient is prepared for skin grafting.

Too often, skin grafting is delayed for

patient and the surgeon, and enables constant inspection of the wound for changes, but does require meticulous care that the surrounding air is clean and contamination is eliminated. It is not suitable for burns that encircle the body.

The standard local treatment consists of the application of a comfortable, firm dressing (Fig. 7), with or without petrolatum fine-mesh gauze as an inner layer. Antibiotics and other chemicals should not be incorporated in this local therapy. Before the burned area is dressed, the wound may or may not be washed or treated. General washing or débridement may be used, but must be carried out gently without anesthesia and, of course, with strict aseptic precaution.

The application of the dressing involves certain principles. The inside layer consists of lengthwise strips, *never* of a circular bandage. Over this, multiple layers of gauze are placed to absorb discharge. A layer of cotton waste under the final outside circular bandage provides elastic pressure.

Most important in the application of the dressing over the burned area is covering the skin well beyond the obviously involved surface in order to be sure that no injured skin will be left exposed to become a portal of entry for infection. The edge of the dressing must also be firmly applied to the skin lest the patient introduce contamination with his fingers. Infrequent dressing is an important principle which will minimize danger of secondary contamination, the possibility of which is increased each time any large, open wound is exposed in an ordinary atmosphere for any length of time. When the open-air treatment is used, such contamination is prevented by isolation, cleanliness, and especially by keeping the exposed surface dry. Once an efficient dressing is applied, it should not be changed for a week or more except when definitely indicated by pain, excessive discharge, or serious infection. The policy of infrequent dressing should be explained to the patient at the outset of treatment lest he mistake it for neglect.

3. *Chemotherapy* plays only a prophylactic role in the treatment of fresh burns. Penicillin and streptomycin in full doses should be given by injection from the very start and continued for at least a week. After the first week, antibiotics should be used when indicated for the control of sensitive organisms and with due regard for the danger of causing diarrhea or other complications if given for too long a time or in too large doses. For a discussion of the indications, hazards, and limitations of chemotherapy see Chapter 5.

4. *Nutritional care* is frequently neglected, as it often is in surgical and other diseases of long duration (Fig. 8). This aspect

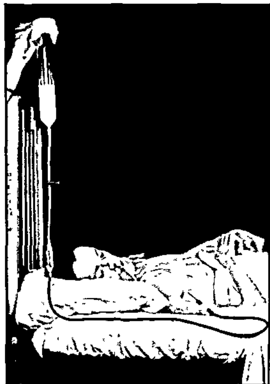

Fig. 8. Malnutrition in a neglected burn. The patient was a 17-year-old boy who was burned a year before. Note the evidence of extreme loss of weight, which had fallen from 150 to 70 pounds. Not shown are the extensive full-thickness burns involving both lower extremities, associated with considerable edema. Note also the arrangement for tube feeding with a tiny plastic catheter which was well tolerated and quite necessary in order to provide an adequate food intake in the face of extreme anorexia. He was also given a total of six injections (3 liters) of whole blood over the course of seven days. The red cell count and hemoglobin concentration, normal on admission, fell after the first two transfusions and then returned to normal. Donor skin from a recently deceased cadaver was then used as a temporary covering. It took and remained in place for several weeks. Later his own skin was transplanted and the patient eventually made an excellent recovery.

amount of physiologic saline plus 2,000 ml. of 5 per cent glucose (for an adult) should also be given. For the second 24-hour period he suggests giving half as much plasma or blood and electrolytes with the same amount (2,000 ml.) of 5 per cent glucose in water. He warns that no more than 4,000 ml. of colloid or 4,000 ml. of saline should be given in a 24-hour period, regardless of the extent of the burn. Evans emphasized that the formula is only a guide to therapy and not an infallible rule. The adequacy of treatment is confirmed by sufficient (25 to 50 ml. per hour) urine output and frequent determinations of the hematocrit or hemoglobin.

2. *Immediate local treatment* in small, first-degree burns consists merely of the application of a comfortable dressing for the protection of the burn after the area has been gently cleansed with warm water and soap. First aid in extensive burns consists merely of sedation when necessary, plus protection of the burn area with sterile dressings and immediate transportation to a site where definitive treatment can be carried out.

The local treatment of burned skin has undergone considerable change in the past one or two decades. In severe burns, scrupulous maintenance of aseptic technic is essential. The mouths of the patient and the personnel must be protected with masks so as to avoid droplet contamination. All steps in the care of the wound should be carried out with the same meticulous care as is used in the performance of a sterile surgical operation. Related to this factor is the importance of infrequent dressings of burns, inasmuch as each time the extensive area is exposed, the likelihood of further contamination is increased.

All forms of local therapy in burns except simple dressings and the open-air treatment (8) should now be considered out-of-date or experimental. The open-air method, without dressing, is certainly the simplest for the

;ical therapy is of decisive importance, ılarly in the extensive burns which re- ;kin grafting (9). Anemia, hypoalbu- ıia, loss of weight, vitamin and hor- deficiencies, all of which develop rap- 'ter severe burns and lead to delayed ; or to fatal complications, are still :valent. Yet they can be prevented, to : extent, by prompt attention to the nu- al needs of the burned patient. During ıte phase, deficits as already discussed be and usually are corrected. Just as :ant, often more so, is the provision of d food intake by mouth, beginning Only rarely will intravenous alimenta- f glucose, amino acids, and vitamins :essary. The diet must be as high in ı as possible, must be easily digestible, ust be easy for the patient to take and :rse to measure. Because of anorexia, ual try is generally inadequate. Much useful are concentrated drinks made :k, skimmed milk powder, or other 'es which, during the critical period, ıtient will swallow despite anorexia. nitial intake may have to be low, per- ·nly 1,000 calories per day, lest gastro- nal disturbances follow. But it must l balanced and contain at least 50 to m. of protein. As soon as possible a intake is reached, which may have to her than normal to correct inevitable ; that have developed during the acute

ɔe feeding may be indicated, especially lected late cases (Fig. 8). In addition ıdequate intake of calories and protein, s evidence that, in burns, large amounts tain vitamins are necessary, owing to ct that they seem to be either utilized, yed, or excreted at abnormally in- d rates, particularly during the active of the burn. Thus, during the first approximately the following amounts ven daily either by mouth or by injec- ıscorbic acid, 1 gm.; thiamine, 20 mg.; ıvin, 20 mg.; niacin, 200 mg.; pyridox- 0 mg.; calcium pantothenate, 100 mg.; ıcid, 25 mg.; and vitamin B_{12}, 25 mg.

Early skin grafting of defects produced rd-degree burns is an important feature in order to restore the patient to full activity as soon as possible, and thus to avoid the evils of a long convalescence. Skin grafting is required whenever nature's spontaneous efforts are faulty, particularly in large defects. Natural healing of lost derma involves replacement by scar, which contains no elastic fibers and no sebaceous or sweat glands and is covered by thin epithelium. Moreover, deformities from contractures are frequent and *cannot* be prevented by holding the part in a natural position forcibly with splints, traction, and the like. Spontaneous healing of deep burns without the use of skin grafts is also defective because of the long period required for final healing. Indeed, large defects may persist for months or years with no evidence of healing.

Preparation for Skin Graft. Elimination of all necrotic tissue is a sine qua non for the application of skin grafts. In extensive burns, the devitalized tissue should be excised down to normal fat, fascia, or muscle in 7 to 10 days if the patient is in condition to stand a formidable operation and can be protected against shock by complete blood replacement (10). Chemical methods, including the use of proteolytic enzymes, have been tried and some of them are promising.

It cannot be emphasized too strongly that once a skin graft is indicated, it should be carried out as soon as possible. Delay merely prolongs disability and increases the nutritional and other complications. Moreover, serious or insidious infection is much more likely to develop. Finally, nutritional rehabilitation may be jeopardized in the presence of a large, granulating skin defect. Coverage of such a wound even with homografts (11) —from a donor or fresh cadaver—greatly accelerates nutritional recovery. Even the temporary life of such grafts is, therefore, of great importance in preparing the patient for final operation, using his own skin. A skin graft is indicated in most full-thickness burns more than 2 cm. in diameter, and on special areas like the fingers, face, feet, and hands, even when the defect is only 4 to 5 mm. in size after separation of the slough.

Skin Grafting. Skin transferred from one part of the body to another is called an autoplastic graft. Skin transferred from one in-

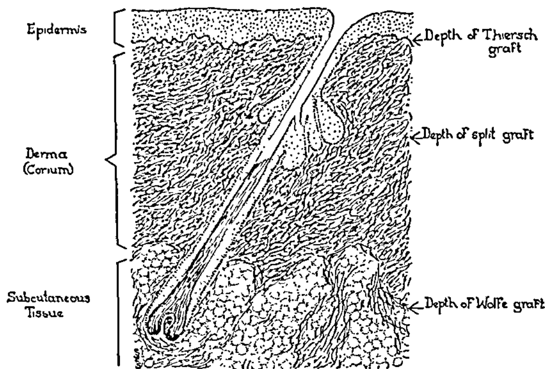

Fig. 9. Cross section of normal skin showing the approximate depth at which the various types of skin graft are cut.

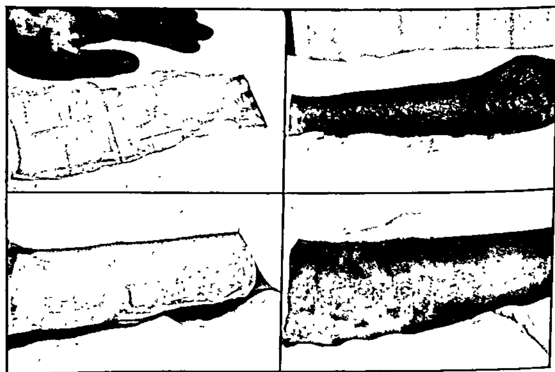
dividual to another of the same species is a homoplastic graft or homograft, which has great value temporarily (see above) but is not permanently successful except in identical twins (11) or in individuals with agammaglobulinemia (12). Skin of different depth may be utilized (Fig. 9). A *free graft* is one in which the transplanted skin is completely removed and transferred to its new location. If the graft, though attached to its new bed, still retains a connection with its original site, the transplant is called a *pedicle graft* or *flap*. As soon as the flap establishes vascular connections with the new bed, the pedicle is cut and the transplantation is complete. This method of transplantation was used 400 years ago by Tagliacozzi. Free transplantation of skin was first performed by Reverdin, a Swiss surgeon who removed tiny pieces of skin (2 to 4 mm. in diameter) from one part of the body and placed them over the granulating defect. The method is still in wide use and can be easily and simply done, but is cosmetically imperfect and heals with much scar between the islands of skin. At the present time there are very few indications for the use of such grafts in the treatment of burns. Thiersch, also a pioneer in skin grafting, described the use of the razor to remove large, thin sheets of skin which included part of the germinative layer but left enough for regeneration to occur. As described and used by Blair and Brown (13), the split graft is a modification of the Thiersch graft and represents a great improvement because the greater thickness results in a graft which is not only more resistant to injury but also presents a more normal appearance. The regeneration which occurs so readily at the donor site takes place by growth of the epithelial cells in the hair follicles and sweat glands just as it does in the case of second-degree burns.

For the coverage of defects produced by deep burns, split-thickness grafts of skin with a dermatome should always be used (Figs. 10, 11). Small pieces of skin cut from a sheet in the form of postage stamps are better than small pieces taken by the Reverdin technic. Pedicle grafts are reserved for some late plastic operations or contractures. When large areas need to be grafted, it is



A B

Fig. 10. Padgett dermatome. A, a "three-quarter" thickness skin graft is being removed from the inner side of the right thigh; the part which has been cut is attached to the drum. B, the graft is being removed from the drum; it is 4 x 8 inches in size, 0.02 inches thick. The patient was a young woman aged 24; the graft was placed in a large denuded aseptic area on her chest. (After Padgett, Ann. Surg.)

important to take with the dermatome not more than 160 square inches at one time and to make them very thin. Thin grafts heal rapidly and, moreover, permit use of the same donor sites over again in about four weeks.

If burns are allowed to heal without the application of skin grafts at the appropriate time (usually 12 to 16 days after the burn),

contraction will develop (see Fig. 12). This contraction can, of course, be corrected by a plastic procedure excising the scar and applying a skin graft in the defect. When this procedure is carried out on the face or neck it is desirable to use a full-thickness graft because it will result in an appearance more nearly like the adjacent skin. In areas covered by clothing, a split-thickness graft is usually satisfactory.

Respiratory Burns. Patients who were trapped in burning buildings, or even in a single room, may suffer severe tracheal and pulmonary injuries from inhaling smoke and flame. The damage may involve the finer bronchioles. In such a fire as that in the Cocoanut Grove night club in Boston, the deaths of scores of patients were due primarily to pulmonary damage induced by the heated air itself or to toxic fumes related to phosgene (14). Some died immediately, others survived for a few hours or a few days at hospitals. Such patients need special therapy directed toward their respiratory symptoms. First consideration must be given to the indications for tracheotomy. Tracheotomy should be done if there is doubt as to its need. This permits direct suction for the relief of respiratory obstruction due to mucus. Humidification of the atmosphere of the patient's room is essential. The use of drugs for bronchial relaxation may also be indicated. Sedatives should be avoided or used with extreme care. Antibiotics will also prevent or control respiratory infection. The danger of excessive intravenous infusions in patients with pulmonary disturbances has already been mentioned.

CHEMICAL BURNS

Caustic alkali, acid, liquid bromine, and other chemicals produce but a superficial injury of the skin provided the contact is momentary. However, the degree of necrosis may be severe if the corrosive chemical is not promptly removed.

Treatment. Emergency therapy, if effective, will minimize the degree of necrosis. Prompt application of large amounts of water to the affected skin in order to dilute the chemical is probably better than any attempt at neutralization by the application of antagonistic substance. Thus Davidson (15), who has investigated the problem experimentally, found much less damage to the skin following the use of plain water than of any other material. The ready availability of water, moreover, also ensures its prompt use. Once the damage is done, the care of the injured area is the same as that for destruction of tissue by any other cause (see under Thermal Burns).

HEAT STROKE AND HEAT EXHAUSTION

These two diseases, despite the similarity in their names, are quite different, as discussed below. Both, however, may be present in the same patient and are due primarily to increases in environmental temperature and are chiefly of medical rather than of surgical interest, except that patients (and also personnel) may suffer therefrom during operations performed during hot weather. All patients should be observed carefully for evidence of heat exhaustion as well as heat stroke during severely hot weather; such preventive measures as ensuring adequate fluid and sodium chloride intake, as well as special nursing care, should be provided. Of even more importance is *the care of the patient in the operating room* during the operation itself; fatalities have been observed, undoubtedly due to the effects of excessive temperature and humidity. Care should be taken that no more sterile sheets be used over the patient than is absolutely necessary. Moreover, the patient must be watched meticulously during the operation, particularly for tachycardia and other evidences of circulatory changes. If such changes are noted, the patient's temperature should be taken. Extensively burned patients are very subject to the harmful effects of hot weather partly due to the loss of the cooling effects of normal perspiration, because of the large dressings and/or of the loss of such function in extensively damaged skin, and partly due to the deleterious effect of high environmental temperature in general on the mortality from burns (16). Hyperthermia generally indicates heat stroke and calls for immediate therapy (see below). Air-conditioning, which is becoming fairly prevalent, solves this problem.

1. *Heat stroke* (thermic fever, sunstroke) is seen during hot weather, especially when the temperature exceeds 100° F. (38° C.). The victims may lose consciousness, present a hot, flushed skin, full rapid pulse, and a high fever which may reach 110° F. (43.3° C.). There is obviously a disturbance of the heat-regulating mechanism. Studies of the blood chemistry showed no marked changes in the patients treated at the St. Louis City Hospital during the hot summer of 1934. A complete clinical study in the nearby city of Cincinnati was reported by Ferris and associates (17). Treatment is urgent and consists of rapid but careful reduction of the fever. Immersion in an ice-water bath is effective. The body temperature is carefully taken every few minutes and the patient removed when it has dropped to 102° F. (39° C.); the fall continues for some minutes. An efficient but slower method consists of covering the nude patient with wet sheets over which air from an electric fan is blowing. Sheets wet with alcohol will be more rapidly effective than those wet with water.

2. *Heat exhaustion*, which in reality consists of severe dehydration and sodium chloride depletion, is seen ordinarily in workmen confined to hot boiler rooms, in heavily clad, marching soldiers, or in any person in whom excessive perspiration leads to loss of water and salt but only water is ingested. This is similar to acute salt deficiency or water intoxication. After states of extreme sweating, McCord and Ferenbaugh (18) state that "in 24 hours the loss from the body of chlorides approximates 20 grams—an amount that certainly may not be replaced by chlorides normally in food and drinks." Victims of heat exhaustion at the Boulder Dam construction were studied by Talbott and Michelsen (19), who found a pronounced reduction in the blood chlorides of these patients. A detailed discussion of sweat losses will be found in a monograph by Kuno (20).

Symptoms come on gradually and include fatigue, cramps of muscles, abdominal pain, and, only in the worst cases, severe prostration. The clinical picture is greatly influenced by physical activity (20) which leads to the first-named symptoms, seldom seen in water intoxication. Even then, the picture is entirely different from that of heat stroke, i.e., the temperature is normal or subnormal, although slight elevations were noted. The skin is moist, pale, and cool and the pulse normal. Treatment is specific—sodium chloride. Heat exhaustion may be prevented by supplying sodium chloride (in the form of tablets) to individuals working under conditions producing excessive loss of body fluids through perspiration.

INJURIES DUE TO COLD

The systemic reactions to cold are those of shock and are produced only under conditions of extreme exposure, which are relatively rare. These accidental instances of hypothermia (21) have assumed wider significance in view of the use of induced reductions of body temperature. Recent studies on hypothermia have added much to our knowledge of this subject. Cardiac arrest and fibrillation are responsible for many of the fatalities, and become increasingly frequent *as the body temperature falls below 28° C.* (79° F.). More common are the local effects —usually on the extremities, nose, and ears —which vary in degree from slight injury to gangrene. Permanent effects are also seen and are of great importance.

Tissue injury, short of actual necrosis, is probably the most frequent effect of cold. Nevertheless, such injury, by secondary factors, may lead to necrosis of tissue. The key to an understanding of those secondary factors is in the vascular as well as in cellular response to cold, particularly when the exposed part is brought into a warm atmosphere. The primary response to the injury produced by cold is, of course, the usual inflammatory changes already described. These changes, however, cannot occur at once because of the cellular paralysis and vasoconstriction which results from cold. Inflammation due to injury from cold can occur only when the temperature returns to normal, i.e., when the chilled part is warmed. Vasodilatation and exudation then take place, swelling becomes marked, and vesicles appear in the skin just as if the part were burned. Much more serious may be the effect of cold on the veins and lymphatics (i.e., thrombosis) which interferes with rapid drainage of fluid. Exudation thus leads to tremendous pressure and swelling in the inflamed area, which may finally become great enough to occlude the arterial supply. As a final event actual gangrene may develop (Fig. 13).

Injury due to cold comprises various clinical types, as follows:

1. *Chilblains* or pernio is a mild inflammatory reaction which develops after exposure to cold, especially damp cold, even when slight in degree. In its severe form, scaling of the skin may follow, and even a local patch of gangrene may appear, which finally heals. *Certain patients are particularly susceptible* to chilblains after previous injury by cold. This may be due to the production of permanent alterations, vascular or neurogenic.

2. *Trench foot* is a form of chilblains seen in soldiers whose feet were exposed to damp cold for many days. It is similar to "immersion foot," described below. Blistering, edema, and areas of gangrene occurred. Healing of these lesions was often prolonged. Such feet often showed more or less permanent disability due to inadequate blood supply and were especially susceptible to further injury from cold.

Fig. 13. Frost bite of the toes. A, three days after exposure; note the marked inflammatory reaction. B, one month later, after spontaneous amputation of the dead tissue. The clean granulating surfaces rapidly epithelialized. Conservative therapy was used, i.e., elevation, rest and heat. The patient was a healthy 31-year-old male.

3. *Frostbite* is a term often applied to any injury due to cold. As used herein it refers to actual necrosis of tissue. Edema, blistering, and (later) evidence of infection may precede the necrosis or gangrene which not infrequently develops; following this, a line of demarcation forms and the dead part eventually sloughs off.

TREATMENT. Proper care of the feet in severely cold weather will prevent most of the ill effects of cold on the lower extremities. This was learned in World War II, especially by Russian soldiers who, in pairs, were required—often at gun point—to massage each other's feet at regular intervals in severe climatic conditions, especially damp cold. Once the part has been injured, the problem is that of preventing necrosis by thawing out all frozen tissue *slowly*. While this may be achieved by the ancient and still popular practice of rubbing the part with snow or cold water, such a procedure is *dangerous* and should not be utilized because it frequently leads to mechanical injury of the frozen tissue, which is friable and easily broken. Gentle heat must be applied carefully so that the skin surface is not injured thereby. Warming with water at 42° C. (104° F.) is a recommended procedure. If warm water is not available, the part can be safely warmed by placing it under dry clothes and against another person's body. Injections of heparin are also recommended and should be started within 24 hours (21).

Of great prophylactic importance, too, is adequate protection against damp and cold, especially in susceptible individuals. The anesthetic effect of cold always makes it a treacherous injurious agent, in that warming is thus impossible. Necrotic tissue is treated as if it were due to any other cause. Amputation is never advisable early in the process. Ordinarily the dead area sloughs off spontaneously, and the area of destruction is much smaller than that originally estimated. After the line of demarcation forms, the rapidity with which the dead tissue is cast off may be accelerated by gentle operative procedures.

Immersion Foot. Described by numerous observers in World War II, this condition is similar to and perhaps identical with the "trench foot" of World War I. The chief manifestation is swelling of the feet, which develops several hours or a few days after exposure to wet cold. It is encountered primarily in shipwreck survivors, particularly those who have been forced to sit in a lifeboat for several days with their feet dangling in cold water. The condition has been described in detail by Webster, Woolhouse, and Johnston (22); it develops only when the temperature of the water is about 55° F. or below, although it may occur in less severe forms with exposure to warmer water.

Clinical manifestations start a day or so after exposure and consist of pain, numbness, and tingling in the feet. Upon examination, they are found to be swollen and pallid, with scattered areas of cyanosis. After removal from the cold environment, swelling tends to increase and the pallidness changes to an erythematous color. The feet become unusually warm but do not sweat. The pulse remains palpable except when edema obliterates it. Blisters, of variable size, containing strawcolored or sanguinous fluid may appear. Local patches of gangrene may develop but are not extensive and usually require no more than local amputation (e.g., of the toes). However, if infection develops in the blisters, abrasions, fissures, and so forth, as it may do, definite threat may be made upon life, and amputation may become necessary.

The exudate of fluid (plasma) into the swollen feet may be so extensive as to lead to shock and, therefore, may actually be a primary cause of death in shipwrecked personnel.

Perhaps the most important feature in treatment is maintenance of a cool temperature about the feet. They should first be washed gently with soap and water to remove dirt, and the like, thereby minimizing the danger of infection. The feet should be kept uncovered and dry. The maintenance of a low temperature is essential because the increased oxidation created by elevated temperature takes place so rapidly that the metabolic demands in the injured extremities cannot be met. Before the patient is allowed out of bed, he should be given graduated exercises. If pain remains, the peripheral nerves may be crushed, as recommended by White (23). This interrupts nerve function

only temporarily inasmuch as regeneration will take place in about three months. However, the condition usually clears up within a few weeks without any special therapy.

Prophylaxis consists of keeping the feet dry and warm with rubber boots. Unfortunately this precautionary measure cannot be made available to all those likely to be set adrift at sea. In addition to keeping the feet dry, application of grease or heavy oil also aids in preventing the disease by acting as a protective covering. Frequent exercise of the extremity is likewise very helpful as a preventive measure. When victims are rescued, they should not be allowed to walk lest the trauma of weight-bearing result in serious damage to the already edematous and damaged tissues of the feet. Prevention of infection is likewise extremely important.

Painful swelling of the feet also occurs in men who are shipwrecked in warm waters. The process does not proceed to as severe a state as in the typical immersion foot syndrome, but may become serious when the victim has been exposed for several weeks. After a study of several cases, White (23) concluded that one of the chief causes of the swelling occurring under such circumstances was a vitamin and protein deficiency. It is assumed that the excess heat, continued exercises (created by bailing, rowing, and so forth), along with dehydration and starvation, result in a vitamin deficiency and hypoproteinemia within a relatively short time.

X-RAY AND RADIUM BURNS

Injurious effects of x-rays and radium are used therapeutically to destroy malignant or other neoplasms. Sometimes normal tissue is intentionally injured in order to achieve this end. Accidental or unintentional burns or injuries to skin by x-ray and radium occurred in the early days of radiotherapy and are still encountered after its inexpert use. The first effects of severe x-ray injury are not evident immediately, but are manifested in about a week or 10 days and consist of hyperemia, tanning, and exfoliation. Serious lesions may occur many years later and consist of indolent ulcerations which do not heal (Fig. 14), become malignant, and lead finally to death. General effects of x-ray therapy also occur within a few hours following a treatment and produce a syndrome which is called roentgen sickness. Nausea and vomiting, asthenia, and headache are the usual symptoms.

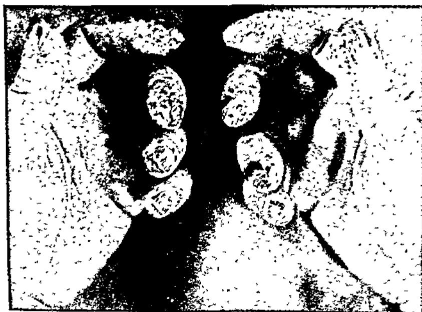

Fig. 14. X-ray burn of hands. This lesion was produced by exposure to x-ray frequently and over a long period of time. Even though exposure is stopped, the lesion may progress and go on to malignant degeneration. (From Deryl Hart in Practitioners Library, D. Appleton-Century.)

Treatment of the ulcerated lesion consists of excision and application of a skin graft. Obviously prophylaxis is most important; use of x-ray and radium should be confined to expert radiologists.

ATOMIC BURNS

Anyone exposed within five miles of the explosion of an atomic or hydrogen bomb may suffer intense burns from heat waves or from ionizing radiation. The former produces effects similar to those of the sun, treatment of which is identical with the treatment of any superficial burn of the same extent and depth (24).

Burns produced by ionizing radiations are very different and cause injuries that have seldom been observed previously except in an experimental animal, which has been given total body x-radiation. When the whole body is exposed to these penetrating rays, internal injuries of a lethal nature follow if the dose is much over 700 roentgen units. The greatest damage is found in the hemopoietic and lymphatic systems, but the gastrointestinal system and all glands are also severely injured. Clinical manifestations consist of nausea, vomiting, purpura, agranulocytosis, and toxemia. Patients who have received sublethal doses may be greatly helped by transfusions, by high protein, high vitamin diets, and by antibiotics. The latter must be given so as not to cause exacerbation of the diarrhea so often associated with the original injury (25). Because of gastrointestinal difficulties, it may be necessary to use the parenteral route to provide nutrition, perhaps for several weeks, until the acute phase is over.

Because of the great numbers of injured persons who might need medical help after an atomic explosion, adequate first-aid transportation and simple mass therapy assume obvious importance and imply the need for careful preparatory organization. This is also true of mass civilian casualties from fire, as evidenced in the tragedy at the Cocoanut Grove in Boston (14). A more recent experience, though with a smaller number of casualties, occurred in Buffalo and has been briefly described (26).

THE EFFECTS OF ELECTRICITY

An electric current in contact with the skin produces reactions which vary widely, depending upon its method of introduction into the body, the voltage, amperage, and kind of current (alternating or direct), on the variety of alternation, and especially on the thickness and moisture of the skin at the points of contact. Obviously, not all electric currents are damaging; many of them have beneficial therapeutic effects and are used in a variety of ways. In general, medium-high voltage currents are the most likely to cause injury.

Accidental electric injuries may be local or general. The *local effects* occur, for the most part, at the site of entrance and exit of the current and, depending on various factors, produce a superficial localized burn or a deep and extensive coagulation of tissue. The necrosis of tissue may be due to the heat generated by the passage of the current or to a direct effect of the current itself. Sometimes the clothes are ignited and typical flame burns complicate the electric injury. Undoubtedly both factors play a role, for even if the local lesion is charred and resembles an ordinary burn, it is apt to become indolent and heal very slowly, suggesting neurotrophic injury. The local lesions are treated as are burns due to any other cause. The extent of necrosis usually is apparent from the grayish color of the damaged skin but may be of much greater extent than first suspected. Tissue beyond an apparently sharp line of demarcation, which appears healthy, may show evidence of inadequate healing weeks or months later. In excising damaged tissue, a wide margin of normal tissue, therefore, should be removed if possible.

The *general effects* of electricity are apt to occur only if the current passes through the central nervous system or heart. Langworthy (27) has studied two electrocuted criminals and found marked changes in the cells of the medullary center concerned with respiration. The clinical manifestations of electric shock are, in most cases, due to respiratory paralysis. Unconsciousness and circulatory impairment are frequently present early. When this happens, artificial respiration must be started within six minutes if the patient is to have any chance of survival. Further treatment is that

of shock in general but, in addition, should include persistent artificial respiration, which should be continued for hours if the circulation is maintained. Obviously, if the medullary cells are merely injured, recovery is possible; if damaged beyond repair, death is inevitable. Since evidence of cerebral edema has been noted, some recommend lumbar puncture and the intravenous injection of hypertonic solutions.

THE EMERGENCY SERVICE AND THE ACUTELY ILL OR INJURED PATIENT

John Schneewind

THE EMERGENCY SERVICE

A well-organized, smoothly running Emergency Service has become an integral part of almost every hospital. This is true not only because acute, severe injuries are increasing due to automobile accidents, and so forth, but because of the obvious need for rapid, efficient treatment for the nonsurgical emergencies as well. Furthermore, every hospital administrator now realizes the need for a carefully organized disaster plan to cope with a sudden influx of many casualties of a tornado, train accident, or the like; the Emergency Service occupies a key position in the management of these patients. The threat of a national disaster due to air attack is another reason for the need of an Emergency Unit as the hub of a disaster plan.

Adequate facilities and personnel are essential to ensure good treatment to the injured or ill patient. The Emergency Service should be in an accessible location where auto and ambulance traffc may be controlled efficiently, and where hospital personnel or anxious relatives will not impede patient movement. Figure 1 illustrates the space set aside for the Emergency Service at the University of Illinois Hospitals. In addition to several examining rooms, there are a nurses' station, a doctors' office, a laboratory, a small x-ray unit, two operating rooms, and two observation wards each containing two beds. These overnight wards are invaluable for allowing repeated examinations of difficult diagr problems and for determining the nee hospitalization. They are also helpful i lowing performance of such ancillary ser as blood transfusions to outpatients du slack periods.

Personnel. It is important that some m ber of the staff be appointed chief of the se ice and be directly concerned with its vari administrative and medical problems. Pr erably, this should be one of the youn members of the surgical staff rather than busy department head. The chief of t Emergency Service should drop in at lea once and preferably several times a day, eve if only for a short time. He may examine a acutely ill patient and assist in establishin the diagnosis, may help with a difficult dis position problem, or may scrub up and assis in suturing a difficult laceration. He must be sure that each hospital department provides adequate coverage for the Emergency Service 24 hours a day. At the Research and Educational Hospitals three interns are assigned to Emergency each month and rotate through eight-hour shifts. During such peak periods as Friday and Saturday nights, a call man is in the hospital and available should the intern on duty be unable to handle the load. A resident from each department is on call at all times for consultation regarding the management of Emergency Service cases. The intern is encouraged to call the resident for all pa-

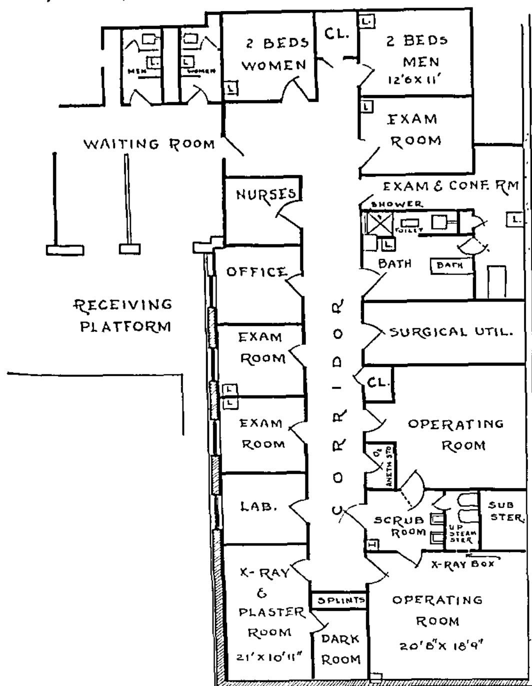

Fig. 1. Floor plan of the Emergency Service at the Research and Educational Hospitals, University of Illinois, College of Medicine.

tients with significant injury or disease. The resident, in turn, calls an attending physician for complicated cases or those requiring a major operation. It should be noted that the majority of cases are handled by the interns and residents and help from the attending men usually is not required.

Emergency Service Manual. One of the problems in maintaining an efficient standard of treatment is the constant rotation of interns each month. We have found it helpful to compile a manual which includes General Rules, Treatment of Wounds, Treatment of Burns, Prophylactic Treatment of Tetanus, a Mul-

tiple Casualty plan, and such miscellaneous items as scrub technique (1). The new interns are met a few days before they go on service and the above material is discussed, together with such other problems as the medicolegal aspect of treatment in the Emergency Room and the management of inebriated patients with head injuries. In addition to our own directives, we have found the monographs on soft tissue injuries and fractures prepared by the American College of Surgeons' Committee on Trauma (2, 3) most helpful.

Although injuries in industry are decreasing in number, accidents in other activities appear to be increasing (see also Ch. 14). For this reason, adequate facilities must be maintained for taking care of emergencies and, of more importance, increased efforts must be made in the teaching of trauma (4).

THE ACUTELY ILL OR INJURED PATIENT

General Considerations. On admission to the Emergency Room, the state of consciousness of the seriously ill or injured patient determines, to a great extent, the amount of information which may be obtained regarding the circumstances of the illness or accident. The prostrate, more or less unconscious patient always presents a complicated diagnostic problem, the solution of which is often urgent because of the necessity of instituting lifesaving treatment. Superficially, such a patient may present a similar clinical appearance whether he is suffering from traumatic shock, alcoholism, diabetic coma, concussion of the brain, uremia, or the like. It is always hazardous to disregard the possibility of intracranial injury merely because the patient has the odor of alcohol on his breath. The sensorial depression may be minimal or there may be complete lack of response to sensory stimulation, in which case the patient is considered to be comatose. A comatose patient, while ordinarily quiet and immobile, may, at times, be restless or exhibit convulsive movements or uncontrolled activity. Such a state may be a sign of cerebral injury or increased intracranial pressure.

In addition to careful evaluation of the state of consciousness, certain other basic principles in the management of acute patients are almost always of great value. Traumatic cases may have a short period in which they are quite responsive and then lapse into profound depression, and the examiner must take advantage of these opportunities. Repeated examination of the patient with a suspected "acute abdomen" is also valuable, since pain and muscle spasm may change significantly in a very short period.

Minimal and gentle handling is axiomatic in treating emergency cases. This is especially true during the initial examination when such an obviously superficial injury as a bleeding scalp laceration may distract attention from a fractured cervical spine or a lacerated spleen due to blunt trauma to the abdomen. Injudicious movement may accentuate shock, stir up quiescent hemorrhage, or cause severe spinal cord damage.

"First things first" is another axiom which must be observed. The cleansing and dressing of a patient with severe burns prior to institution of treatment of burn shock may spell disaster. Treatment of obvious fractures while active hemorrhage from a lacerated spleen proceeds undetected is an error too commonly made.

It is advantageous, perhaps, to attempt to classify some of the diseases which are capable of producing more or less complete loss of consciousness and other evidence of sensorial dysfunction, since they may present difficult diagnostic problems.

I. Circulatory Shock

This may produce severe prostration and varying degrees of cerebral dysfunction due to the general circulatory impairment and cerebral anemia. Some of the causes are:

1. Hemorrhage
2. Trauma, including fractures
3. Burns
4. Exposure
5. Myocardial infarction and heart failure
6. Cardiac tamponade

II. Intracranial Lesions

These may produce more evident sensorial depression, often coma and convulsions, and sometimes restlessness and delirium. Such disturbances are due to actual cerebral injury or obstruction to

outflow of cerebrospinal fluid and may be caused by:

1. Trauma
2. Apoplexy or vascular spasm
3. Embolism
4. Tumors
5. Infection

III. Physiochemical Coma

This group is concerned with the effect of deranged intrinsic physiology or extrinsic poisons on the cerebral cells. Included are:

1. Alcoholism, poisons
2. Diabetic coma, insulin shock
3. Uremia due to urinary obstruction (enlarged prostrate, stone, etc.), kidney disease
4. Dehydration and electrolytic depletion due to vomiting, diarrhea, fistulas, starvation, etc.
5. Severe illness due to septicemia, advanced intestinal obstruction, gangrene of the extremities, hepatic disease, and severe jaundice
6. Various types of psychoses

Further details concerning these three groups will be found in Table 1, which lists many of their pathologic and clinical differences. A more complete description will be given in the text after considering some gen-

TABLE 1. The Acutely Ill or Injured Patient (Common Causes of Sensorial Depression)

	Shock	Intracranial Lesions	Physiochemical Disease
Etiology	Hemorrhage Trauma, including fractures Burns Myocardial infarction Heart failure Cardiac tamponade	Trauma to brain tissue and increased intracranial pressure; i.e., injury, hemorrhage, edema, tumor, infections	Poisoning, uremia, profound infections and toxemia, dehydration, hypoglycemia and hyperglycemia, psychosis, asphyxia, hepatic disease, electrolyte depletion (i.e., sodium, chloride, and potassium)
Pathogenesis	Low blood pressure due to low blood volume or ineffective propulsion	Direct brain damage; cerebral anemia due to increased intracranial pressure	Toxic action on brain; abnormal cerebral function
Clinical picture	1. Low blood pressure 2. Fast, thready pulse 3. Respirations may be *shallow; air hunger in* hemorrhage 4. Subnormal temperature 5. Slight to moderate sensorial depression 6. Restlessness and thirst in hemorrhage 7. Pallor 8. Collapsed veins	1. Varied blood pressure 2. Full pulse; may be slow 3. *Irregular respirations* 4. Normal or elevated temperature 5. Coma, hyperactivity, convulsions 6. Pathologic neurological signs 7. Choked disk 8. If traumatic, scalp lacerations, fractured skull, etc. 9. Abnormal spinal fluid	1. Normal or high blood pressure 2. Full pulse; may be fast 3. Variable respirations (Cheyne-Stokes, air hunger, etc.) 4. Normal or elevated temperature 5. Deep coma, convulsions, delirium 6 Special signs as revealed by odor of breath, bladder dullness and rectal examination, urine and blood examination, etc. 7. In sodium and potassium depletion, may have hypotension and/or mental apathy even to coma
Emergency treatment	Clear airway Control of hemorrhage, rest, warmth, sedatives, fluids, transfusion, oxygen	Clear airway Intravenous fluids and transfusions as indicated	Gastric lavage, insulin, glucose, catheterization, fluids (especially sodium and potassium), artificial respiration, lumbar puncture, etc.

eral points in the physical examination of these prostrate patients.

PHYSICAL EXAMINATION OF THE ACUTELY ILL OR INJURED PATIENT

It is essential that the Emergency Room physician master the technic of a rapid yet thorough examination of the acutely ill patient. Although detailed examination is impossible, it is surprising how much information can be obtained by a systematic approach.

Initial Inspection. In the initial inspection, the examiner should look for evidence of severe illness or injury requiring immediate attention. If there are no indications for immediate therapy, the physician may proceed with a more detailed examination as described below. Cardinal points of crucial importance are:

1. *Is the Patient Breathing?* The examiner must be sure the tongue is forward and that vomitus, mucus, or blood is not blocking the airway. The presence of a collapsed lung due to pneumothorax or severe chest injury may be the very first thing to treat.

2. *Is the Patient Bleeding?* Immediate control of obvious accessible hemorrhage by a pressure dressing is mandatory.

3. *Is the Patient in Shock?* With airway cleared and hemorrhage controlled, intravenous administration of fluids such as dextran, plasma, or whole blood is required to treat circulatory deficiency, usually present or imminent in a severely injured patient.

4. *Is There a Severe Wound?* Severe wounds require immediate attention, especially when there is acute bleeding. The bleeding must be controlled by a pressure dressing or temporary application of a tourniquet in the case of a severed artery in an extremity. If the airway is clear and shock therapy has been instituted, the following points should be ascertained:

a. Time Interval. The extent of elapsed time since infliction of the wound will affect the method of treatment.

b. Location and Extent. The severity of trauma is influenced by the size and location of the wound in relation to nearby vital structures. Small neck wounds may cause respiratory obstruction or injury to blood vessels, cervical cord, pharynx, or esophagus. Thoracic injuries may fracture ribs, sever intercostal or mammary vessels, or penetrate lungs, heart, trachea, or esophagus. Penetrating injuries low in the chest commonly lacerate spleen, stomach, liver, and colon. Abdominal wounds may involve such retroperitoneal structures as kidneys and vena cava as well as the intraperitoneal viscera. Wounds in the extremities may involve tendons, nerves, and large vessels.

c. Type of Wound. It is important to note whether the wound is blunt or penetrating in type and whether it is a clean, incised wound or a crushing injury with severe contamination. Puncture and human bite wounds are usually not primarily sutured, in contrast to incised wounds of recent origin.

5. *Is There a Fracture Deformity?* Inspection may reveal swelling, echymoses, or an obvious deformity. Point tenderness, false motion, crepitus, bony irregularity, and loss of function are other signs of a fracture which may be present. Multiple rib fractures may be associated with intrathoracic injury and bleeding into the pleural space, with pneumothorax due to puncture of the lung, or, in very severe injuries, with a flail chest and paradoxical respiratory motion.

6. *Is Sensorium Affected?* It has been noted above that loss of consciousness may be due to some pre-existing disease or to intracranial trauma at the time of injury. At any rate, the state of consciousness is often an index of the seriousness of the illness or injury.

Brief History. After the cardinal points relative to the vital processes of respiration and circulation have been ascertained, a rapid, brief history of the accident or illness should be obtained from the patient by direct questioning if he is able to respond coherently. It may be necessary to obtain the information from a witness to the accident or from a member of the family. Important points which must be established are: 1. state of consciousness prior to and following injury or illness; 2. pre-existing disease or disability; and 3. previous treatment rendered—especially relative to administration of narcotics. If, for example, the patient has sustained a head injury, inability to recall the

details of the accident or transient loss of consciousness may be the initial sign of significant brain injury associated with extradural or subdural bleeding. In the case of gunshot or stab wounds, it is important to establish the relative positions of assailant and patient in order to get an idea of which organs may have been injured. It is also obvious that a past history of coronary thrombosis, stroke, diabetes, and the like, may change the whole method of diagnosis and treatment of the current episode.

Orderly, Thorough Examination. The physician should do a rapid, thorough examination now that he knows that the patient's life is not in immediate danger and he has some idea of what he may encounter and what aspects of the examination will require an assiduous search. The routine of examination is not as important as the consistency in following some systematic method. One method is to begin with pulse, temperature, respiratory rate, and blood pressure (if not already determined). Not only the rate but the force and rhythm of the pulse should be checked. Color, temperature, and moisture of the skin should also be noted.

HEAD AND NECK. Inspection and palpation of the scalp for possible lacerations or fractures may be followed by systematic palpation of facial bones and mandible, especially if there is a history of head or facial trauma. The relative size of pupils, response to light, fixation of gaze, and color of scleras may then be noted. Ears and nose should be checked for bleeding or for leakage of cerebrospinal fluid. Mouth and tongue are inspected for lacerations, loose teeth, bleeding, and so forth.

Injury to the cervical spine may be revealed by visible or palpable deformity, tenderness, and echymosis. The presence of such an injury requires a rapid motor, sensory, and reflex examination. Prior to any movement of the patient, the head must be supported to prevent lateral deviation or torsion. In the absence of cervical spine injury, the neck may be flexed to determine whether rigidity or tenderness is present. Further examination of the neck may reveal enlarged lymph nodes, tracheal deviation, hematomas, or emphysema. The head should be flexed for determination of neck rigidity or tenderness.

THORAX. Inspection of the chest should include notation of rate and depth of respiration, and asymmetry or inequality of expansion such as is found in significant pneumothorax, massive collapse, or large pleural effusion. The bony framework including clavicles, ribs, and spine should be inspected and palpated. The patient may be gently rolled from side to side for this purpose, but not if he has a fracture of the spine. Auscultation and percussion of lungs and heart may then be done.

ABDOMEN. Examination of the abdomen may begin with palpation of the costovertebral angles to elicit tenderness over the kidneys. Compression of the pelvic girdle may cause pain if there is bone injury. Inspection of the abdomen may reveal distention caused by intestinal obstruction, ascites due to cirrhosis, peritonitis, metastatic cancer, and so forth, or localized tumor masses. Palpation should always proceed from the least tender area to the painful area and must always be gentle. Localized muscle spasm may be a sign of acute appendicitis or cholecystitis; rebound tenderness usually denotes inflammation of the parietal peritoneum. A globular, tender, right upper quadrant mass may be a hydrops of the gallbladder caused by a blocked cystic duct. Each quadrant of the abdomen should be examined, using bimanual palpation when necessary to help the examiner feel liver, spleen, kidneys, and so forth. Character and rate of bowel sounds and presence of bruits, as in abdominal aortic aneurysms, may then be determined. The presence of ventral, inguinal, or femoral hernias may be noted; for this purpose it may be necessary to have the patient stand, assuming that no contraindication for this position is present.

GENITALIA. When a gynecologic examination is indicated, the external genitalia should be inspected and palpated, followed by speculum examination of the vagina and cervix. A gram stain of vaginal secretions may reveal gram-negative intracellular organisms, which is very helpful in the differentiation of acute appendicitis from pelvic inflammatory disease. Significant tenderness on moving the

cervix also indicates pelvic inflammation. Bimanual examination of uterus and adnexa should be included. In males, the scrotum should be inspected and palpated for evidence of orchitis, epididymitis, hydrocele, tumors, and the like.

RECTAL EXAMINATION. A rapid inspection of the anal verge may reveal external hemorrhoids, fistula, or fissure. Digital examination should note sphincter tone and may reveal intraluminal or extraluminal masses due to tumors or an inflammatory process. Metastatic growths may produce a shelflike projection of the anterior rectal wall. In women, the rectovaginal septum, and in men, prostate and seminal vesicles, should be felt.

EXTREMITIES. Simple inspection of an extremity may be diagnostic if there is obvious deformity, loss of function, swelling, or ecchymoses. Some of these signs are usually present if the injury is significant. The presence of cyanosis, edema, or the red streaks of lymphangitis should be noted. Palpation should show the presence of arterial pulses and, in the case of bone injury, may reveal local tenderness, false motion, crepitus, or muscle spasm. These maneuvers must be performed very gently.

In the case of lacerations and other wounds of the hands and fingers where tendon or nerve injury may be present, a most painstaking examination is necessary to evaluate correctly the extent of injury. The location of the wound is a valuable guide to the examiner. In injuries to the deep flexors of the fingers, there is inability to flex the distal phalanx; however, the examiner must immobilize the middle phalanx to obtain an accurate test. Similarly, inability to flex the distal phalanx of the thumb when the proximal phalanx is held immobile indicates a severed flexor pollicis longus tendon. In the case of wounds in the proximal finger area or palm, lack of flexion with the metacarpophalangeal point fixed indicates that both tendons have been cut.

Severed extensor tendons near the knuckles are common and, in this case, the patient cannot hyperextend the metacarpophalangeal joint with the interphalangeal joints flexed (as in striking a piano key). If an extensor tendon is cut near the distal interphalangeal joint, the patient may exhibit the so-called mallet finger deformity, i.e., the inability to extend the distal phalanx. In injuries of the thumb, if there is inability to extend the distal phalanx with the proximal phalanx immobile, the long extensor has been severed. If the patient suffers injury to the motor branch of the ulnar nerve in the palm, he will be unable to abduct or adduct the fingers when they are placed on a flat surface due to loss of interosseous muscle innervation. There also will be inability to "sweep" the thumb across the palm to the base of the fifth finger due to loss of the adductor pollicis muscle. If the motor branch of the median nerve is injured, the patient will be unable to lift the thumb normally or oppose it to the finger tips due to loss of short abductor and opponens muscle function. The usual sensory distribution of the ulnar nerve to the fifth and ulnar side of the fourth finger, and median to the rest of the digits, enables the examiner to assay possible injuries to sensory nerves.

If the patient's illness is due to involvement of the brain and spinal cord, a rapid neurological examination may be performed. For significance of findings, therapy, etc., the reader is referred to Chapter 27.

Acutely ill children and infants may comprise an appreciable percentage of the patients brought to the emergency service. Details of the examination of these young patients may be found in one of the standard pediatric textbooks.

SIGNIFICANCE OF COMMON ABNORMAL FINDINGS

General Appearance. As noted above, the initial rapid observation should reveal the presence of hemorrhage, shock, or asphyxia, for each requires prompt emergency treatment. The skin, if pale and cold, indicates shock; if cyanotic, suggests cardiac or respiratory disease; if grayish and pale, lead poisoning. The breath is frequently a great source of information. The sweet odor of acetone, the fetid breath of uremia, or the fecal odor in late intestinal obstruction may suggest the correct diagnosis at once.

Changes in the Sensorium. Sensorial changes indicate the degree of coma and can be determined by the response elicited by

such stimuli as pressure over the supraorbital nerve, the corneal reflex, or dilatation of the rectal sphincter. Hysterical patients, for example, will seldom fail to react to one or the other of these stimuli. In shock, unconsciousness is slight and ordinarily the patient will respond to such simple stimuli as pinching the skin. Deep coma with no response may indicate profound shock but is more commonly due to cerebral injury, uremia, or poisoning. Delirium or convulsive movements (especially in children) may accompany coma in severe infections, intoxication, or disease of the brain. In psychoses, the coma will be inconstant and often accompanied by peculiar behavior. In head injuries, an uncontrollable hyperactivity sometimes amounting to actual mania may be present. It is also seen in psychoses. In most instances, the depth of the coma, however, has been of little diagnostic aid (Solomon and Aring, 5). Increased intrapericardial pressure (cardiac tamponade) due to hemorrhage from wounds of the heart usually produces a delirium with muscular hyperactivity. Electrolyte depletion may result in depressed sensorium, especially in potassium loss (6), or even in coma, especially in sodium chloride loss (7).

Changes in Respiration. Abnormal breathing sometimes gives a clue as to the diagnosis. A very slow rate, five or ten respirations per minute, suggests morphine poisoning. Rapid, shallow respirations are common in shock; those deep and eager (air hunger) may indicate serious hemorrhage but are most notable in diabetic coma as a symptom of acidosis. Irregular breathing, such as Biot's or Cheyne-Stokes, indicates a cerebral lesion, either traumatic or secondary (cerebral edema) to an infection or uremia. When respirations are forced and accompanied by exaggerated use of all the accessory muscles of respiration, a physical obstruction is probably present in the larynx or trachea (exudate, spasm, edema, foreign body, or tumor), and explains the cause of cyanosis. Cyanosis and increased respiratory rate may be manifestations of cardiac disease; dyspnea and orthopnea may give the clue. Pulmonary edema or pneumonia may also cause an increased respiratory rate; pulmonary signs may be present on examination of the chest.

Changes in Temperature. A body temperature below normal points to shock; it is elevated, of course, in most severe infections, although in sepsis the low point may be subnormal, usually in the morning. An unusually high temperature is found in sunstroke and occasionally in intracranial lesions, particularly in terminal stages.

Miscellaneous Signs. Numerous miscellaneous signs may be of much diagnostic value. Argyll-Robertson pupils (lost reaction to light with retention of accommodation) point to tabes; pinpoint pupils to morphinism. In deep coma, however, examination of the eyes is apt to be unrewarding, since the pupils are often abnormal, regardless of the cause (Solomon and Aring, 5); this is true also of the reflexes. Ophthalmoscopic examination may reveal papilledema, indicative of increased intracranial pressure; retinal hemorrhages are present in nephritis, diabetes, etc. Hemorrhage from the ears or nose, especially the former, suggests basal fracture of the skull. Scalp lacerations may accompany or reveal a fracture of the skull; there may be an escape of cerebrospinal fluid or actual brain tissue in the wound. Cerebrospinal fluid draining from the nose or ear indicates a serious injury to bone and meninges because of the location at the base of the skull. Mouth burns indicate the swallowing of caustic poisons; spasm of the masseter muscle, laryngeal spasm, and risus sardonicus point to tetanus. Stippling along the gums (lead lines) are diagnostic of lead poisoning. Percussion of bladder dullness may indicate prostatic obstruction. This is made more plausible by the palpation of an enlarged prostate per rectum; catheterization may yield a liter or more of urine in such cases. Gastric lavage may reveal contents indicative of poison. Neurological signs indicative of disease of the brain and spinal cord should be looked for in questionable cases. Important are the sensory and motor disturbances when obtainable.

Laboratory Tests. Frequently, laboratory tests are the only means of making a diagnosis. Examination of urine, usually obtained by catheter, may reveal sugar (diabetes), casts, albumin (nephritis), pus (infection),

or blood (bichloride poisoning). The usual routine blood examinations are carried out and may show a high red cell count in dehydration, shock, and polycythemia, or a low count in hemorrhage. Stippling of the red cells indicates lead poisoning; plasmodia are diagnostic of malaria. Leukocytosis is present in serious infections and leukemia. Blood may be examined also for its sugar content to determine whether hypoglycemia or hyperglycemia is present. In uremia there will be an increased nonprotein nitrogen content of the blood. The blood chlorides paradoxically may be low in dehydration when there has been excessive loss of intestinal secretion from vomiting, diarrhea, and the like. A white cell count may be indicated in acute appendicitis. The serum amylase test may be very helpful when acute pancreatitis is being considered, as a high reading is usually diagnostic. It must be realized that moderate elevations are frequently encountered in intestinal obstruction and perforations of the gastrointestinal tract and must be interpreted correctly so that operative intervention, when indicated, is not delayed.

CIRCULATORY SHOCK

Although an entire chapter has been devoted to the subject of shock and hemorrhage, some of the cardinal points may bear repetition. Such obvious trauma as hemorrhage from severe lacerations, penetrating wounds of the chest or abdomen, fractures, and burns will be the cause of shock in most patients brought to the Emergency Service. The cause of shock in patients with blunt trauma to the thorax and abdomen is usually more difficult to diagnose and may be due to injuries to the spleen, kidney, or liver, or rupture of a hollow viscus such as gastrointestinal tract or urinary bladder. The onset of shock may be insidious in these patients and repeated examinations by an alert physician are required for early diagnosis. It is axiomatic that shock should be treated as early as possible, since the patient responds much more readily if treated before the manifestations have become prominent.

Conditions other than trauma which may cause shock, or at least a shocklike state, are insulin hypoglycemia, anaphylactic reactions, heart failure due to myocardial or coronary disease, and overwhelming infections.

Clinical Manifestations of Shock. The general appearance of the typically severe case is that of a seriously ill patient. The skin is cold, wet, and pallid; the extremities are cold; the lips are pale. The sensorium may vary from moderate dullness and apathy to a semicomatose state. Peripheral circulatory impairment is characterized by collapsed veins, rapid, thready pulse, and falling blood pressure. Temperature is often down a degree or two and respirations may be shallow and rapid. Hematocrit determination may be normal or reduced depending upon the mechanism of the shock. In the cases of shock due to hemorrhage, the hematocrit will be reduced if hemodilution has occurred as a compensatory effort to restore circulating blood volume. The white cell count often rises a few hours after trauma, especially when hemorrhage has occurred.

Treatment of Shock. It is possible to outline certain principles in the treatment of shock, but these must be modified in any specific case depending upon the clinical cause. The patient in acute heart failure will not tolerate large amounts of intravenous fluids whereas this may be lifesaving in the acute burn patient.

1. PREVENTION OF SHOCK. The early signs of impending shock may be very minimal. Slight tachycardia, perspiration or a feeling of faintness following positional change (as after sitting up), restlessness, or thirst may be all that is present, but should be honored by prompt institution of intravenous therapy.

2. CONTROL OF HEMORRHAGE. Obvious, accessible hemorrhage usually can be controlled by occlusive dressings. Tourniquets are rarely indicated and may cause damage if not released every few minutes. Bleeding from the lung following a penetrating injury usually will subside in a short time but must not be confused with hemorrhage from the chest wall, which may require operative intervention. Prompt celiotomy is almost always indicated in cases of intraperitoneal bleeding, whereas retroperitoneal hemorrhage, including that of the contused or lacerated kidney, is usually best treated by careful observation in the early period following injury.

3. Intravenous Fluids. Whole blood remains the colloid of choice in the treatment of shock due to hemorrhage; however, a plasma expander is an excellent substitute during the period of typing and crossmatching. It is usually quite safe to administer up to 2 liters of plasma expander, but additional needs should be furnished by whole blood. Slaney (8) has shown experimentally that, although one of the plasma expanders is very effective as a blood substitute following moderate hemorrhage, subsequent bleeding must be treated by whole blood infusion, especially when operation is contemplated. Animals receiving large quantities of plasma expander showed reduced tolerance to surgical stress when compared with animals resuscitated with whole blood. Saline and glucose may be used with at least temporary benefit if blood, plasma, or expander cannot be obtained immediately. Glucose alone is contraindicated because it results in rapid loss of electrolytes; moreover, the water injected without salt is poorly retained.

Other measures which may be helpful include conservation of body heat, bed rest, and relief of pain. Although theoretically the dilatation of cutaneous vessels might add to the circulatory imbalance, the patient usually feels better if cold, wet clothing is removed and he is given warm blankets. Bed rest is very important. Even moderate movement of a patient close to decompensated shock will precipitate sweating, tachycardia, and a fall in the blood pressure. Relief of pain by appropriate splinting of injured extremities and the judicious use of sedatives or analgesics may also be helpful.

INTRACRANIAL LESIONS

Most of the important intracranial lesions seen in an emergency room are traumatic. When severe symptoms are produced immediately, direct damage to the brain is usually present. Not infrequently, however, symptoms develop more slowly because they are due to a secondary rise in intracranial pressure (see Ch. 27).

Increased intracranial pressure produces symptoms not only because of the direct effect of pressure on nerve centers or tracts but also because of the associated cerebral anemia which it produces. Convulsions, when they occur, are probably due to cortical stimulation, usually by the same lesion causing the increased pressure. Uncontrollable hyperactivity is also seen in head injuries and is presumably due to the same cause.

Etiological Factors. The traumatic and nontraumatic causes of increased intracranial pressure are listed below. Much of our present knowledge of the physiologic reactions to increased intracranial pressure is based on the early observations of Harvey Cushing (9).

1. *Trauma,* i.e., head injury involving brain damage (concussion or laceration), with or without skull fracture, is frequently followed by increased intracranial pressure because of active bleeding (intracranial or extradural), because of subdural escape of cerebrospinal fluid, or because of cerebral edema which often follows trauma to brain tissue.

2. *Apoplexy* or spontaneous *intracranial hemorrhage* is an obvious cause of increased intracranial pressure. When a small vessel within the substance of the brain bleeds, the hemorrhage is not great and recovery of consciousness may be rapid. On the other hand, the outcome in severe cases is rapidly fatal.

3. *Infections,* i.e., meningitis (pyogenic, tuberculous, syphilitic), encephalitis, and tetanus may produce increased intracranial pressure by (*a*) inducing an edema of the brain tissue itself or by (*b*) obstructing the flow of cerebrospinal fluid by exudate or adhesions.

4. *Neoplasms* increase intracranial pressure by their actual growth within the rigid cranial cavity or by interfering with the flow of cerebrospinal fluid. When cerebral neoplasm is the cause of sudden unconsciousness, hemorrhage into the tumor is usually the primary factor in its production.

Clinical Manifestations. In head injuries, a history of trauma is usually obtained. Evidences thereof are lacerations and contusions of the scalp, crepitus or depressions of the skull itself (hematoma, however, may simulate a depressed fracture), bleeding from the ears or nose, or escape of cerebrospinal fluid. A roentgenogram may be necessary to detect fracture. Further examination is directed toward eliciting positive neurologic signs.

or blood (bichloride poisoning). The usual routine blood examinations are carried out and may show a high red cell count in dehydration, shock, and polycythemia, or a low count in hemorrhage. Stippling of the red cells indicates lead poisoning; plasmodia are diagnostic of malaria. Leukocytosis is present in serious infections and leukemia. Blood may be examined also for its sugar content to determine whether hypoglycemia or hyperglycemia is present. In uremia there will be an increased nonprotein nitrogen content of the blood. The blood chlorides paradoxically may be low in dehydration when there has been excessive loss of intestinal secretion from vomiting, diarrhea, and the like. A white cell count may be indicated in acute appendicitis. The serum amylase test may be very helpful when acute pancreatitis is being considered, as a high reading is usually diagnostic. It must be realized that moderate elevations are frequently encountered in intestinal obstruction and perforations of the gastrointestinal tract and must be interpreted correctly so that operative intervention, when indicated, is not delayed.

CIRCULATORY SHOCK

Although an entire chapter has been devoted to the subject of shock and hemorrhage, some of the cardinal points may bear repetition. Such obvious trauma as hemorrhage from severe lacerations, penetrating wounds of the chest or abdomen, fractures, and burns will be the cause of shock in most patients brought to the Emergency Service. The cause of shock in patients with blunt trauma to the thorax and abdomen is usually more difficult to diagnose and may be due to injuries to the spleen, kidney, or liver, or rupture of a hollow viscus such as gastrointestinal tract or urinary bladder. The onset of shock may be insidious in these patients and repeated examinations by an alert physician are required for early diagnosis. It is axiomatic that shock should be treated as early as possible, since the patient responds much more readily if treated before the manifestations have become prominent.

Conditions other than trauma which may cause shock, or at least a shocklike state, are insulin hypoglycemia, anaphylactic reactions, heart failure due to myocardial or coronary disease, and overwhelming infections.

Clinical Manifestations of Shock. The general appearance of the typically severe case is that of a seriously ill patient. The skin is cold, wet, and pallid; the extremities are cold; the lips are pale. The sensorium may vary from moderate dullness and apathy to a semicomatose state. Peripheral circulatory impairment is characterized by collapsed veins, rapid, thready pulse, and falling blood pressure. Temperature is often down a degree or two and respirations may be shallow and rapid. Hematocrit determination may be normal or reduced depending upon the mechanism of the shock. In the cases of shock due to hemorrhage, the hematocrit will be reduced if hemodilution has occurred as a compensatory effort to restore circulating blood volume. The white cell count often rises a few hours after trauma, especially when hemorrhage has occurred.

Treatment of Shock. It is possible to outline certain principles in the treatment of shock, but these must be modified in any specific case depending upon the clinical cause. The patient in acute heart failure will not tolerate large amounts of intravenous fluids whereas this may be lifesaving in the acute burn patient.

1. PREVENTION OF SHOCK. The early signs of impending shock may be very minimal. Slight tachycardia, perspiration or a feeling of faintness following positional change (as after sitting up), restlessness, or thirst may be all that is present, but should be honored by prompt institution of intravenous therapy.

2. CONTROL OF HEMORRHAGE. Obvious, accessible hemorrhage usually can be controlled by occlusive dressings. Tourniquets are rarely indicated and may cause damage if not released every few minutes. Bleeding from the lung following a penetrating injury usually will subside in a short time but must not be confused with hemorrhage from the chest wall, which may require operative intervention. Prompt celiotomy is almost always indicated in cases of intraperitoneal bleeding, whereas retroperitoneal hemorrhage, including that of the contused or lacerated kidney, is usually best treated by careful observation in the early period following injury.

depression (or hyperactivity such as delirium and convulsions) is produced by a disturbed cerebral physiology, as occurs in the psychiatric diseases, poisoning, uremia, etc. The classification is not exact, however, because the coma in uremia is sometimes due as much to an associated cerebral edema as to direct toxic injury to the brain itself, as shown by the occasional, though transient, improvement following lumbar puncture (Christian and O'Hare, 14). The wet, edematous brain is a well-known lesion in alcoholism; in very acute cases, lumbar puncture has also been used therapeutically (Williams, 15).

Diagnosis and treatment are urgent, of course, in patients who have ingested poison or are suffering from carbon monoxide poisoning. In the former case gastric lavage is instituted at once to rid the stomach of as much of the poison as possible. A large tube is necessary in order to effect rapid evacuation and to allow the use of large volumes of fluid; this cannot be done efficiently with a small tube. In carbon monoxide poisoning, artificial respiration with a gas containing a high percentage of oxygen and also carbon dioxide is indicated. The former is necessary because of the need to replace CO from the hemoglobin molecule as rapidly as possible, so that gaseous metabolism can occur normally. Carbon dioxide acts as a respiratory stimulus which also aids in overcoming the deficiency in oxyhemoglobin in these cases. The treatment of asphyxia has already been described. If a laryngeal obstruction is present, intubation or tracheotomy is lifesaving. Comatose patients are particularly liable to asphyxia due to relaxation of their pharyngeal muscles and obstruction due to the tongue falling back over the larynx; aspiration of vomitus is likely for the same reason. The prone position is therefore safer in comatose patients, or care must be exerted to pull the tongue forward and to apply suction to the throat. In diabetics, the prompt use of insulin and intravenous alkali (in the form of sodium lactate and Ringer's solution with or without glucose) may be lifesaving in the most severe cases. On the other hand, in hypoglycemia, intravenous glucose is specific. Severe dehydration and electrolyte deficiency require the adequate administration of fluids (containing the appropriate electrolytes) parenterally, which will relieve the symptoms rapidly.

Depth of coma is determined by noting the *effect of stimuli of varying intensity.* The circulation is observed at intervals for, although unchanged at the onset of the injury, it may undergo alterations which are frequently diagnostic of a steadily increasing intracranial pressure. Thus, a *slowly bleeding middle* meningeal artery produces an extradural hematoma that increases the intracranial pressure progressively. The resulting cerebral anemia stimulates a reflex increase in the general blood pressure designed presumably to force more blood into the anemic brain. However, this leads to further extradural bleeding. As the general blood pressure rises, the pulse rate falls and may become slow (40 to the minute). Such an increase in blood pressure apparently occurs only from localized *arterial bleeding of this type.* Another sign of middle meningeal hemorrhage is the so-called "lucid interval." This period represents a temporary restoration of consciousness occurring between the initial unconsciousness, due to the accident, and that produced by the slowly forming hematoma. *Eventually, the circulation fails and death* ensues unless operation relieves the situation.

Lumbar puncture in the presence of increased intracranial pressure is condemned by many surgeons because of the danger of medullary compression at the foramen magnum. It is, nevertheless, widely used in trau*matic cases and serves a diagnostic purpose* by revealing the presence of bloody fluid. This may be of medicolegal importance when the x-ray of the skull is negative. It also serves to decrease intracranial pressure. The authors, however, do not recommend lumbar puncture as a routine procedure. Its danger can be lessened or eliminated by using a manometer and avoiding the loss of cerebrospinal fluid.

The relation of skull fracture to intracranial injury is an inconstant one, i.e., fracture may be present without evidence of brain damage, or it may be absent with serious injury to the cerebrum (10). A demonstrable skull fracture is of great importance medicolegally. The *various aspects of intracranial* injury are discussed under skull fractures in Chapter 27.

Frequently comatose patients with meningitis of one kind or another are brought into an emergency receiving room. There may be an elevation of temperature and leukocytosis to suggest the presence of infection, and a rigid neck or positive Kernig's sign to point to meningeal irritation. A lumbar puncture usually reveals abnormal fluid. The eyegrounds may show a swelling of the disks.

In such slowly increasing intracranial pressure as occurs typically in brain tumor, three cardinal symptoms occur, i.e., headache, *vomiting, and choked disk.* Convulsions may occur. Localizing symptoms of neurological nature depend on the location and type of tumor; a discussion of them belongs to special works on brain tumors (Pilcher, 11 and Davis, 12).

Treatment. In general, therapy is directed *toward the cause of the brain injury* or of the increased pressure. In traumatic cases, the detection of middle meningeal hemorrhage demands immediate craniotomy in order to evacuate the clot and ligate the artery. When a depressed fracture is present, operation is also indicated, but rarely is a decompression advisable. *Usually, however, the* treatment is conservative and is directed toward reduction of the intracranial pressure by intravenous hypertonic saline or glucose and lumbar puncture. Morphine is not to be given since it masks cerebral symptoms and depresses respiration. If persistent convulsions or hy*peractivity are too intense,* chloral hydrate, paraldehyde, or sodium amytal are given. Wechsler (13) has reported *that severe* convulsions which fail to respond by other means will often cease following the intravenous injection of 1 ml. of paraldehyde. If lumbar puncture reveals cloudy fluid, the patient is presumably suffering from a pyogenic meningococcus meningitis and appropriate anti*biotics are given,* even before the organism is identified. In other infections, the treat*ment is nonspecific. Apoplexy* is treated symptomatically; the increased intracranial pressure, though difficult to control, requires no special treatment. In brain tumor the treatment is neurosurgical.

PHYSIOCHEMICAL COMA

The diseases in this heterogeneous group have in common the fact that the sensorial

infections around important structures with disastrous results. Most important in deciding if primary tendon repair should be attempted is the length of time since injury. Although the antibiotics have possibly prolonged the time factor, four to six hours (10) is now considered the limit for primary tendon repair. This limit might be overstepped somewhat, depending on the wound and the circumstances under which it was received. If in doubt, it is much better judgment merely to close the skin and delay repair until a later time. A sharp lacerated wound sustained under favorable conditions, such as in the home, heals readily and is quite different, for example, from a crush injury. A crush wound causes damage over a wide area, blood vessels are thrombosed and tissues have such reduced healing powers they can scarcely survive. Badly torn and crushed skin flaps rarely survive. Under such circumstances it is much better judgment to delay definitive repair of deeper structures.

General anesthesia is needed for all except trivial injuries because (*a*) the patient does not tolerate long the constriction of the pneumatic cuff and (*b*) procaine infiltration of the hand, where there is little areolar tissue, impairs healing and decreases resistance to infection. A bloodless operative field is essential in order to see clearly and identify small structures. This is obtained by applying a blood pressure cuff to the upper arm, elevating the arm for two minutes to allow venous blood to empty, and inflating the cuff to 280 mm. of mercury. The cuff should be applied loosely so as not to obstruct venous return when the arm is elevated.

Careful attention to surgical technic will decrease scarring. Simply to know how to make incisions, repair tendon, and obtain hemostasis is not sufficient. Each structure must not only be accurately identified but handled with the greatest gentleness. The wound is kept moist by frequent saline irrigations and the finest instruments used. Blood vessels are ligated with fine sutures, care being taken to include only the blood vessel itself and none of the surrounding tissue.

Injuries to the Covering Tissue. Except for certain special considerations, the treatment of simple lacerations of the hand is the same as that applied to open wounds elsewhere (Ch. 14). Exclusion of tendon and nerve injury is necessary first by careful examination of function. There should be no probing or picking at the wound; the diagnosis is made entirely by examination of function. The size of the wound has no relation to its gravity; it is possible to divide all the structures on the dorsum of the wrist through a 2-cm. stab wound. At the time of initial examination, the wound is appraised as to the need for skin grafts or flaps because, if covering tissue is inadequate, repair of deeper structures may be contraindicated.

Tendon division can occasionally be diagnosed by noting the posture of the fingers on the arm board; e.g., division of one or more flexor tendons in a finger allows it to fall into extension; division of an extensor tendon allows the proximal phalanx to drop into flexion. Mechanical cleansing with soap and water is the most effective method of decreasing contamination, the importance of antiseptics being greatly overemphasized. A sterile dressing is put over the wound, the forearm and hand shaved and fingernails cut short. After washing the surrounding skin, the dressing is removed and the wound cleansed with a second sterile setup.

The principle of block débridement, i.e., excision of the entire wound to render it free of bacterial contaminants is not only unnecessary in the hand but impossible to perform (9). Furthermore, it is important that no tissue be sacrificed, especially skin unless it is devitalized. Proper débridement is accomplished by cutting away all tissue which has been deprived of its blood supply. Dead space is obliterated by carefully placed sutures and the skin is closed without tension. The application of a pressure dressing of fluffed gauze and immobilization of the hand on a splint are of great importance in promoting healing.

Avulsions. Tangential wounds of the hand may avulse a portion of the skin and result in a long flap, the distal part of which may be nonviable. This is especially likely if the base of the flap is located distally, a so-called retrograde flap. When there has been actual loss of tissue, the scarcity of subcutaneous tissue in the hand prevents skin approximation without undue tension on the

17

THE HAND

WILLIAM REQUARTH

Surgery of the hand is discussed in a separate chapter for several reasons. 1. Fingers and hands are more prone to injury because their prehensile function places them constantly in contact with the outside world, particularly in individuals doing manual labor. Even slight injury is often sufficient to introduce an invading organism that may already be present in the folds and crevices of the skin. 2. The manifold and delicate functions of motion in the hand, so essential in many kinds of manual activity, are particularly impaired by injury and infection which may produce serious and even permanent disability. The reasons are many; an important one is the poor blood supply to the fingers, as they are composed mostly of tendons, nerves, bone, and tough connective tissue. There is, therefore, little space for swelling, for increased blood flow, for exudation, and for leukocytic invasion, all of which are necessary in nature's response to injury. 3. There is a distressing tendency for infections to spread, not only by direct extension into neighboring spaces and tendon sheaths but particularly into lymphatics and into the general blood stream. Moreover, serious infection may follow hand injuries, even with the advent of chemotherapy. It is not surprising, therefore, that special study and care are essential, particularly since hand injuries and infections offer a tremendous challenge in that proper treatment can achieve a good final functional result, whereas ill-advised treatment, which is unfortunately too common, may be ineffective and even harmful.

There are a number of monographs devoted to this field to which the reader is referred (1, 2, 3, 4). The experiences with hand surgery in World War II also was extensive and contained many details of value in civilian surgery (5).

INJURIES OF THE HAND

The disability following even trivial wounds of the hand is considerable and may cripple the hand, resulting in an economic loss to the individual far out of proportion to the severity of the injury. Good functional results are best obtained by accurate anatomic repair at the time of injury; results of secondary repair weeks later being much less satisfactory. Wounds have been discussed in detail elsewhere (Ch. 14). Many of these factors apply to hand injuries, but there is sufficient difference and the initial care of the wound of such importance that the care of the injured hand demands separate consideration.

General Principles in Treatment. There are general principles in the treatment of the injured hand which must be closely observed if satisfactory results are to be obtained (6, 7, 8, 9). The details of treatment vary considerably among different surgeons and will not be considered (10, 11, 12). Scar and fibrosis are the greatest deterrents to a good functional result and all the factors which produce them—as hemorrhage, dead tissue, and damage due to rough operative technic—must be carefully avoided. Perhaps the most important cause of scarring is postoperative infection. For this reason, primary healing is an absolute essential for satisfactory end results. The lack of loose areolar tissue in the hand confines even low-grade

sutures, yet *the wound must always be closed.* Raw areas left open become covered with granulation tissue and require weeks to heal. During this extended period of nonuse, loss of function may result; constantly exposed tendons usually become necrotic and are extruded. For these reasons, when caring for the injured hand it is extremely important that the surgeon always close the wound, if not by simple suture, by a skin graft or local flap. Although as much skin as possible should be saved, it is a serious surgical error to replace a flap of skin which may not be viable. Such flaps seldom survive, quickly become necrotic, and must eventually be excised, thus delaying the whole process of healing. Under circumstances when the viability of the skin is in doubt, it is better judgment to excise it and cover the wound with a skin graft.

A free skin graft (one not attached by a pedicle) is suitable for covering a raw area. The best graft for use in surgery of trauma is the intermediate-thickness or razor graft (13, 14, 15) (Fig. 1). It can be cut easily from the volar surface of the forearm or the medial aspect of the thigh with a Blair knife (16), dermatome, or even a small, straight razor. It is important that the graft be only part-thickness although this can be varied. The thick-split (17) graft resists injury better and has a more normal appearance than the thinner graft; however, with this graft it is more difficult to get a good "take." If the surface is clean and the blood supply good the graft may be thick; poor blood supply and the possibility of infection require the use of a thinner graft even though the eventual cosmetic result may not be as good. Intermediate-thickness grafts will close the wound and give primary healing, and if further reconstructive surgery is necessary, it can be planned at a later date. The important point is not to leave the wound open. Free grafts of full-thickness skin should not be used unless one is skilled in their use.

A pedicle flap of skin and subcutaneous tissue is used where bone, raw tendon, or nerve is exposed, since a free graft grows poorly on such a surface. Occasionally, adjacent skin can be used as a *rotation flap* (Fig. 2) especially on the dorsum of the

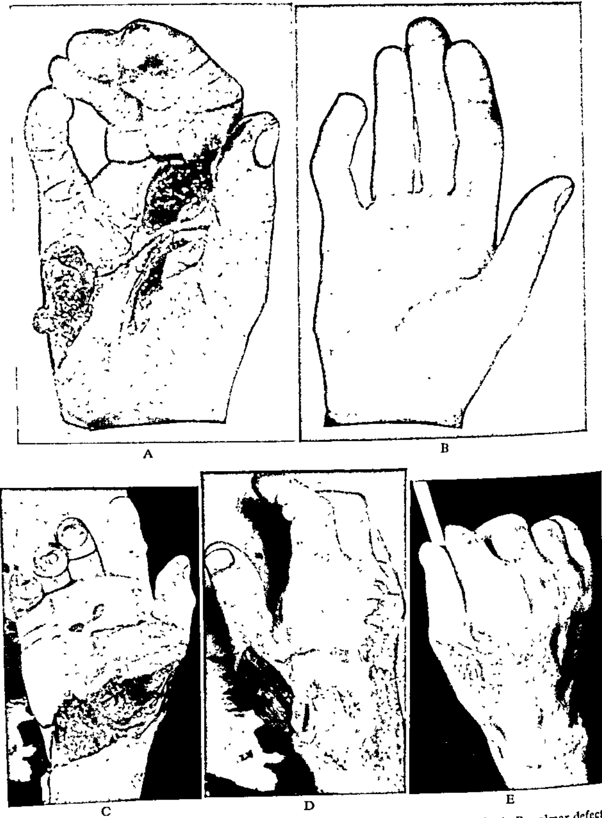

Fig. 1. Traumatic skin defects of hand repaired with intermediate thickness graft. A, B, palmar defect result of planing machine injury. C, D, E, skin loss after corn picker injury. The skin on the dorsum was intact but not viable and therefore excised and replaced with a free graft.

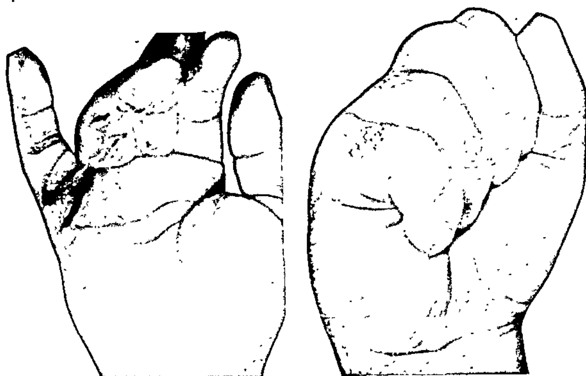

Fig. 4. Division of both flexor tendons by knife wound. Injury occurred with hand in closed position; the proximal tendon was easily retrieved without need of an additional incision.

langeal joint is possible through the action of the lumbrical and interosseous muscles.

The position of the divided tendon ends may often be predicted. If divided at or distal to the metacarpophalangeal joint with the fist clenched, the distal portion of the tendon is short and far distal but the proximal fragment is long and easily retrieved (Fig. 4). If the injury occurs with the fingers extended, the distal portion is long, the proximal fragment of the tendon is short and may retract as far as the carpal tunnel or even the wrist (Fig. 5). Determination of the position of the tendon ends prior to operation aids in the planning of incisions.

Adequate surgical exposure of the divided tendon is rarely possible through the laceration itself. The laceration should be enlarged from each end; e.g., extending a transverse laceration of the finger proximally and distally along the ulnar and radial aspects of the finger just dorsal to the flexion creases. When possible, the incision should be planned so that a flap of skin and subcutaneous tissues is formed which will cover the line of suture. Incisions should never cross flexion creases nor be placed down the mid-line of the finger because of the danger of contracture.

If both flexor tendons are divided in the digital sheath, it is advisable to excise the sublimis as far distally and proximally as possible and *repair only the profundus* since satisfactory function is possible through the action of this tendon alone. Repair of both tendons when divided in the digital sheath usually results in adhesions between the tendons and a poor result. Function after repair of flexor tendons divided at the level of the middle or proximal phalanx is often unsatisfactory even when expertly done; the prognosis for return of function improves as the level of division moves proximally, e.g., to the palm or wrist.

There are many variations in the technic of suturing tendons, but fine silk or wire is the suture of choice (Fig. 6). Knots should not be allowed to interpose between tendon ends, and the finest caliber of suture material that will maintain opposition should be used. When several adjacent tendons are involved, care must be exercised in identifying the ten-

Flap is raised and transferred in one operation, detached after 14 days. Below, avulsion of soft tissue of thumb in grinder. It is important to preserve length of thumb whenever possible.

hand. When skin and subcutaneous tissue are needed and a local flap cannot be devised, it is then best to raise and transfer an abdominal pedicle flap (13, 18, 19) (Fig. 3).

Injuries to Tendons. Tendon repair should be undertaken immediately in all cases when conditions are favorable, but there are several distinct contraindications to primary tendon repair. It has been noted that repair undertaken beyond the time limit of six hours after injury is hazardous because of the possibility of infection. Tendons should not be repaired in wounds contaminated by tooth injuries and others inoculated by bacteria. Crush injuries are unsuitable for tendon repair as are wounds which have received meddlesome first aid and sent in for operation later. There must be adequate covering tissue and no skin defect present. Finally, the surgeon should understand the technic of tendon repair and have the proper facilities to undertake it. If conditions are not right for primary tendon repair it is much better judgment merely to close the skin and undertake secondary repair at a later time. Division of the flexor tendon in the digital sheath overlying the middle and proximal phalanges is followed by such poor results that primary repair here should be attempted only under the strictest conditions (20, 21).

Flexor Tendons. Deep flexor tendons and the flexor pollicis longus insert at the bases of the distal phalanges and their division causes inability to flex the distal phalanges when the middle phalanges are held in a fixed position. The flexor digitorum sublimis inserts at the base of each middle phalanx and flexes the proximal interphalangeal joints. However, even with both flexor tendons divided, flexion at the metacarpopha-

dons and attaching the correct segment of the central to the correct segment of the distal end.

Soon after repair, the tendon ends soften so that sutures tend to pull out. Because the holding power of tendon for suture is low, heavy silk of high tensile strength is useless and actually harmful because of its irritating quality. It is much more important to use fine sutures and to keep the wrist and metacarpophalangeal joints flexed on a splint to prevent tension on the suture line. A fibrinous cuff forms at the site of healing and, after the second week, fibers grow from one tendon to the other to form a strong union (22, 23). During this time if motion is allowed, the tendon is irritated by stretching and tends to enlarge and become ovoid in shape. Therefore early

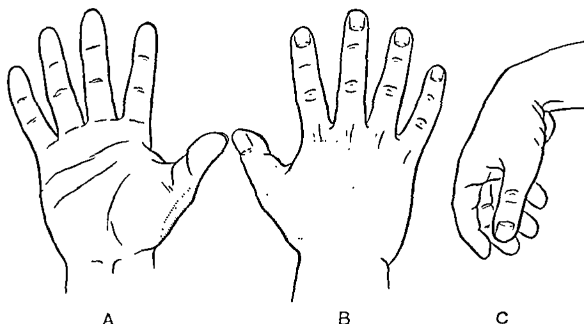

Fig. 8. Sensory and motor findings in radial nerve paralysis. A, sensory changes on the palmar surfac B, sensory changes on the dorsal surface; C, wrist drop due to motor paralysis.

wire to prevent retraction. Secondary suture is deferred until a later time.

Division of the *radial nerve* at the elbow or higher causes wrist drop plus inability to extend and abduct the phalanges of the thumb. There is occasionally temporary sensory impairment in an area between the first and second metacarpals (Fig. 8). Division of the posterior interosseous branch of the radial nerve results in inability to extend the fingers and thumb but the wrist extends to a neutral position through the action of the extensor carpi radialis longus. The posterior interosseous nerve is often damaged during surgery in the region of the head of the radius.

Division of the *median nerve* in the lower forearm or wrist produces anesthesia of the radial part of the palm, the thumb, the index and middle fingers, and the medial half of the ring finger (Fig. 9). Paralysis of the thenar muscles prevents opposition of the thumb to the base of the little finger (Fig. 10). In old, untreated median nerve paralysis, the skin is shiny and atrophic, the thenar eminence flattened, and the thumb pulled close to the hand by the unopposed adductors (Fi 11).

Division of the *ulnar nerve* at the wrist re sults in paralysis of all the interossei, the ac ductors of the thumb, and the two ulnar lum brical muscles. The patient is unable t

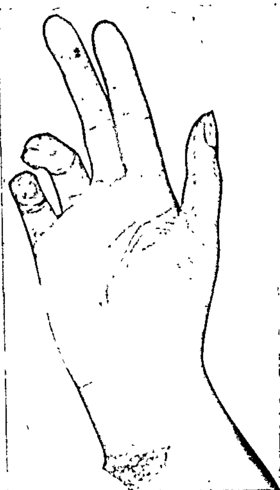
Extenso tendon is part of aponeurosis in distal part of dorsum of hand and minimal retraction of tendon end occurs. Below, left and right, injury by knife wound proximal to extensor aponeurosis. Maximun retraction occurs and supplemental incision (I) is necessary to retrieve tendon.

motion after tendon repair actually increases the chance for a poor result. Immobilization is continued for three weeks after which limited use is allowed and after five weeks the splint is removed.

EXTENSOR TENDONS. Extensor tendons are not enclosed in a sheath on the dorsum of the hand, being loosely attached to one another through areolar tissue and the dorsal aponeurosis. They retract very little and after repair gliding motion is easy to restore. Results are good and repair is not difficult (Fig. 7). Frequently an extensor tendon may heal spontaneously without suture if the finger and wrist is kept splinted in extension for several weeks. Because the extensor tendons do not communicate with any major space of the hand, infection following primary repair is never as serious as after flexor tendon repair. For these reasons, the indications for primary repair are more liberal. After repair, the metacarpophalangeal joints in the wrist are splinted in extension for five weeks.

Injuries to Nerves. The diagnosis of division of peripheral nerves is made by careful examination of disturbances in tactile sensation in the palm and fingers by means of a pin and a piece of cotton, and also by examination of the motor function of the small muscles of the hand. Immediate primary suture of nerve is usually possible, the conditions of time, degree of contamination, and amount of damage to surrounding tissues being more liberal than those for tendon. Under unfavorable conditions, the nerve endings may be drawn together with a single suture of fine



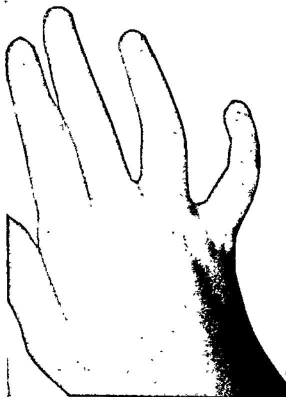


Fig. 13. Ulnar nerve paralysis. Left, knife wound of wrist with typical deformity of ring and little fingers. Right, paralysis after fracture of humerus. Recovery was spontaneous. Note hyperextension of proximal phalanges of ring and little fingers and flexion of distal.

prognosis following repair is poorest in such mixed nerves as the ulnar nerve, and is best in the radial, which is nearly all motor. The median occupies the middle ground, being mostly sensory with some motor fibers to the thenar region.

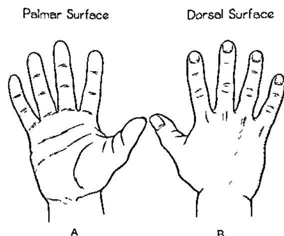

Fig. 14. Areas of anesthesia in ulnar nerve paralysis.

Return of sensation nearly always occurs after repair of the median and ulnar nerve whereas the outlook for return of motor function is much more uncertain. Other factors affect the result of nerve repair, e.g., the amount of scar tissue that forms between the nerve endings and the length of time that the paralysis has existed prior to repair. When the paralysis has existed for more than two years, the muscle atrophy and degeneration are pronounced and usually permanent. The time required for return of function after satisfactory surgical repair depends upon the distance from the point of suture to the actual nerve endings and may be a year or longer.

During World War II, the results of primary nerve repair were so unsatisfactory that

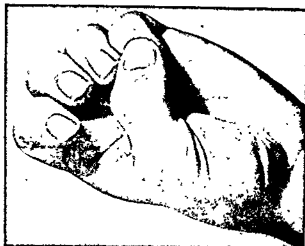

Fig. 10. Motor test for median nerve palsy. With fingers flexed and metacarpophalangeal joints held in extension, patient is asked to place thumb on nail of little finger. Thumb must rotate across palm because action of intact flexor pollicis longus can closely simulate opposition of thumb.

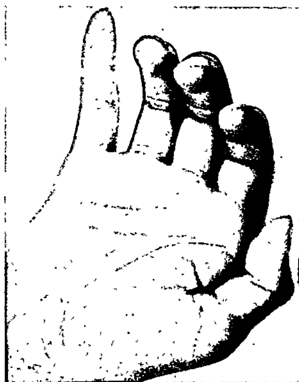

Fig. 11. Old median nerve paralysis. The paralyzed thenar muscles are atrophic, thenar eminence flattened and thumb pulled close to hand by unopposed adductors.

Fig. 12. Motor test for ulnar nerve palsy. Patient is asked to abduct index finger against examiner's forefinger. The first interosseous muscle (arrow) contracts if motor fibers are intact.

spread the fingers or adduct the thumb (Fig. 12). The classic deformity of ulnar paralysis is hyperextension of the metacarpophalangeal joints of the ring and little fingers and flexion of their proximal interphalangeal joints. Normally, the lumbrical and interosseous muscles flex the finger at the metacarpophalangeal joints and extend the distal phalanges. Because all of the interossei and the two ulnar lumbricals are paralyzed to these fingers, the unopposed common extensor extends the proximal phalanges and long flexor tendons flex the distal phalanges, producing the "claw hand" deformity (Fig. 13). There is sensory loss of the skin over the ulnar third of the palm and the ulnar half of the fourth finger and all of the fifth finger (Fig. 14).

Return of function after nerve repair depends upon the growth of the axons into the distal segment of nerve. In mixed nerves, i.e., sensory and motor, it is extremely important that the nerve ends be united without axial rotation because this results in motor axons growing into sensory axons, and vice versa. The chance of axial rotation is greatly decreased in fresh injuries, especially if the nerve has been divided tangentially or has a small blood vessel on its surface and the ends can be "matched." However, some degree of rotation always occurs and for this reason the

those of the first group are usually simple, the rest more complicated.

Chemotherapy, when used early, can greatly decrease the virulence of infection and eliminate many complications. However, the antibiotics have not eliminated the need for good surgical principles in the care of infection. As in other fields of surgery, the control of infection is based not only on accurate diagnosis but also upon identification of the organism. Antibiotics are most effective in bringing under control the acute spreading infections unless the infection is caused by an organism not sensitive to the antibiotic used. It is true that the antibiotics occasionally abort an infection in the early stages, e.g., a felon, but more often incision and drainage are necessary. Where localization has occurred, antibiotics have no effect except perhaps to help keep it localized.

1. SUPERFICIAL INFECTIONS. These infections of the hand are similar to those occurring elsewhere and are caused by puncture wounds or other injuries. Only the skin, or at most the subcutaneous tissue, is involved. Although arising outside such structures as the closed space, tendon sheaths, or fascial spaces, they have a tendency to extend or penetrate into them. It is important, therefore, here as well as in any hand infection to examine the structures repeatedly for extension of swelling or tenderness. Drainage of the pus by an incision sufficiently shallow to avoid tendon sheaths and nerves is often necessary.

Carbuncle of the hand is a term used to describe multiple abscesses of the furuncle type with a cellulitis affecting the dorsum of the hand. The infection is deeper, however, than in furunculosis. Adequate drainage, usually by cruciate incision, is usually indicated.

2. PARONYCHIA. This is a less serious type of infection located under the eponychium and about the root of the nail; hence its name paronychia. The infection is usually spontaneous although a history of injury of hangnail is sometimes obtained. The forerunner of the subungual abscess (paronychia) is the eponychia, a small bleb of pus alongside the nail with no subungual extension. If neglected, the pus spreads toward the opposite side and burrows beneath the nail to become a subungual abscess (Fig. 16). Because of its tendency to extend along the base of the nail to the other side it is often called a "run-around."

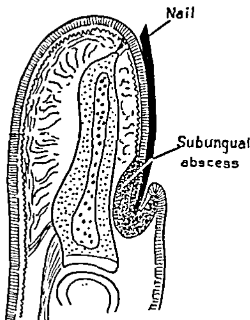

Fig. 16. Paronychia and subungual abscess. Longitudinal cross section of terminal phalanx showing the superficial location of the abscess beneath the cuticle, as well as the deeper (subungual) portion which is covered by the proximal part of the nail.

The treatment of any eponychia is to evacuate the bleb of pus and cut away part of the overlying skin to ensure drainage. It must be emphasized that this treatment will *not cure a subungual abscess, and to use it in* hope that more radical measures will not be necessary only prolongs the disability. A subungual abscess is suspected when an eponychia fails to heal or when pressure on the nail causes pus to exude. Adequate drainage of a subungual abscess is obtained only by complete removal of the proximal one third of the nail. Two parallel incisions are made extending proximally from the base of the nail, the flap thus formed is elevated, and the nail is removed. One should be certain that no nail fragments are left at the angles to act as foreign bodies and cause drainage. A piece of petrolatum gauze is laid under the flap for 24 hours and the finger immobilized on a simple tongue blade splint.

Suppuration occasionally persists despite

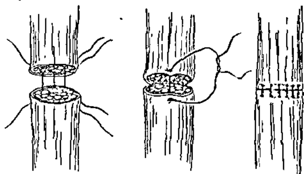

Fig. 15. Technic of nerve suture. (Redrawn from Koch.)

some advocated delayed secondary repair three to six weeks after injury (24, 25). It was thought that the poor results might be due to difficulty in approximating the freshly cut nerve ends and also that better axon penetration would result after the reaction of degeneration was completed. A controversy arose which is not yet settled (25). It would seem that immediate repair is preferable when possible; and, if secondary repair is necessary because of contamination or other factors, it should be done soon (26).

The nerve is sutured with interrupted fine sutures of No. 000000 black silk, being *careful to place the needle only through the perineurium* and to avoid trauma to the nerve *endings by rough handling.* As many as 12 to 16 interrupted sutures are inserted to obtain accurate approximation (Fig. 15). The wrist and hand are splinted for six weeks in a position which allows no tension on the suture line since the repair is for approximation alone and has little holding power.

If paralyzed muscles are allowed to be continuously overstretched by the action of unopposed antagonists, function is frequently poor even after regeneration of the divided nerve. Because nerve regeneration may require a year or longer, the patient should wear a splint during this period to support the paralyzed muscles in a position of physiologic rest. For example, radial nerve division requires a splint which will hold the wrist in dorsiflexion and the thumb extended and abducted from the hand.

ACUTE HAND INFECTIONS

Since many serious hand *infections begin* as trivial skin injuries which serve as a portal of entry for virulent bacteria, it should be *emphasized that* prompt and effective treatment of such lesions must be carried out in each case. Each scratch or break in the skin, no matter how small, should be immediately cleansed, a surface antiseptic applied, the lesion protected with a sterile dressing, and the part immobilized for a day or two (27). This simple treatment *will prevent a large percentage of the severe infections* and cannot be too strongly urged as a routine, particularly in shops and factories where such injuries are common.

Types of Infection. It is important to differentiate between acute spreading infections of the hand and localized collections of pus which are often the sequelae of the former. Spreading infections may follow simple abrasions with moderate swelling, redness, and surrounding cellulitis. The process may extend and red lines of lymphatic involvement may appear on the forearm and arm with enlarged and tender epitrochlear and axillary lymph nodes. Such an infection is still *spreading* through the tissues and responds best to chemotherapy and antibiotics. It is *important to avoid* premature incision and thus open fresh plains of tissue to the spread *of infection,* an error which can be fatal. Although delay in draining a localized infection *may permit destruction* of tissue with consequent severe disability, it is safer to await *unquestionable localization* rather than to risk incision into a spreading infection.

Of the various types of localized infections, perhaps the most serious are acute tenosynovitis *and palmar and* bursal infections, not only because they are more frequently associated *with septicemia* but also because the local manifestations are so intense. The *entire hand becomes swollen, stiff,* and immobile in a position of slight flexion. Extreme *disability frequently follows* such infections, even when the healing process is complete. *A septic hand is not infrequently* complicated by lymphangitis, lymphadenitis, and thrombophlebitis. *Other lesions may* occur as later complications; e.g., osteomyelitis, suppurative *arthritis, and gangrene.* In the following description of the various types of infection,

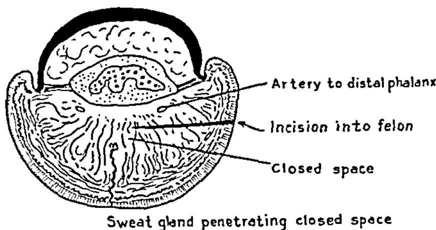

Fig. 19. The relation of the closed space to the bone and arteries supplying it. Transverse section showing also a sweat gland to illustrate one method by which the closed space may be invaded without apparent trauma. The proper method of incision into the closed space for the drainage of a felon is also indicated.

of an osteomyelitis must be taken for granted. Eventually, dead bone (sequestrum) separates and may have to be removed, but even then the end result is a deformed, sometimes painful, and often useless terminal phalanx.

Early incision into the closed space on one or both sides of the finger is urgently indicated (28). Chemotherapy should be used concomitantly, but rarely alone as the definitive therapy. The incision is never made through the pad of fat on the palmar surface, which is a specialized end organ containing a great concentration of sensory endings. Such an incision, while theoretically the most direct approach to the closed space, often produces hyperesthesia or actual pain in the healed scar because of cicatricial contraction of the many delicate nerve endings in the pad of fat. The proper incision is on the lateral aspect of the phalanx, carrying the knife inward and dividing the fibrous bands with a sweeping motion (Fig. 19). In order to avoid

Fig. 20. Web space infection between ring and little fingers. Left, abduction of involved finger is characteristic; *middle*, relatively minor infections cause marked edema of dorsum of hand; right, drainage by transverse incision in palm. (After Requarth in S. Clin. North America.)

Fig. 17. The connective tissue closed space. *Radiograph (redrawn from Dorrance) after injection of red lead to show the extent and location of this potential space.*

drainage. Prolonged drainage is most frequently the result of failure to remove the base of the nail. Occasionally, chronicity is due to a fungus infection, which is to be suspected when healing does not follow the therapeutic procedures just described. In such instances the use of fungicides may be helpful.

3. FELON. "Felon" (sometimes called whitlow) is a term which should be limited to an infection of the anterior closed space of the terminal phalanx, although it is loosely applied to any serious finger infection, especially when the bone is involved (Fig. 17). This "closed space" is located in the deeper portion of the pulp end of the finger and contains fatty tissue supported by numerous fibrous strands radiating from the periosteum of the bone to the periphery. It has no communication with the joint or tendon sheaths, although the flexor tendon inserts nearby at the base of the bone. Infection frequently develops spontaneously or whenever appropriate virulent organisms are introduced either by puncture of a sharp object, by direct extension from an overlying infection of the skin covering the finger pad, or by way of a *sweat gland.*

Exudation, one of the first manifestations of infection, distends this closed space within a few hours. Since there is little room for swelling, the tension becomes great and pain exquisite. The pain is of a throbbing character, made much worse with the hand in a dependent position. Tenderness is intense, but redness and swelling only slight (Fig. 18). Diagnosis and treatment, even at this early stage, is important lest the viability of the underlying bone be jeopardized by the increase of pressure within the closed space on the nutrient artery supplying it. At times, it is advisable to incise this space even though diagnosis is not definite, so important is early drainage. In the severe and neglected cases this may lead to a massive necrosis (osteomyelitis) of the entire phalangeal bone. This complication may not be detected objectively until radiologic changes occur, which take a week or two. Unless the pressure is relieved by early incision, the ultimate development

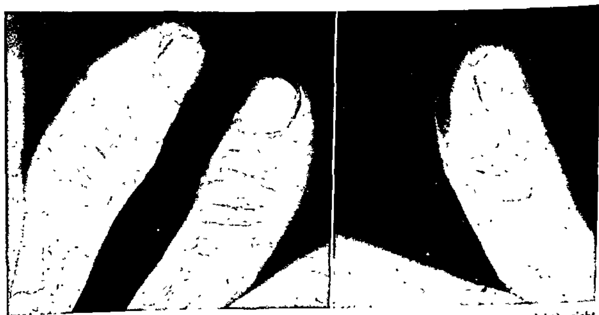

Fig. 18. Felon of left thumb. Left, swelling is scarcely perceptible (normal thumb on right); right, after incision and drainage. (After Requarth in S. Clin. North America)

and swollen and there is a hard, indurated mass in the web which holds adjacent fingers in extreme abduction. The abscess is drained through a transverse incision in the distal palm (Fig. 20).

5. ACUTE TENOSYNOVITIS. This infection is limited to the flexor tendon sheaths of the fingers and usually follows trauma, frequently of a very minor character. Moreover, it is not necessary that the injury penetrate the tendon sheath, since the infection may be carried to it by lymphatics or by direct extension through the sheath. It is a dangerous infection, because 1. it may lead to necrosis of the tendon with its resultant disability; and 2. it may spread directly along the sheath into the hand and forearm.

The flexor tendons lie in fibrous tunnels which bind them to the volar surface of the phalanges and prevent them from bowing outward during flexion of the finger. They are lined by synovial sheaths whose anatomical arrangement divides sheath infections into two groups. The sheaths of the index, middle, and ring fingers end in a blind pouch in the palm at a level of the metacarpophalangeal joints, a point which corresponds to the distal palmar flexion crease if projected into the palm. Pus tends to gravitate to this blind pouch, called the cul-de-sac, and may rupture into the thenar space if the index finger sheath is involved, or into the palmar space if the ring finger sheath is infected. The sheath of the middle finger usually ruptures into the palmar space but can also involve the thenar space.

The sheath of the flexor tendon of the thumb extends proximally to the wrist but enlarges in the palm to form the radial bursa (Fig. 21). The flexor tendon of the little finger likewise extends to the wrist and also enlarges in the palm, this portion being called the ulnar bursa and encloses the flexor tendons at the wrist. The two bursas usually communicate with one another so that it is possible for an infection in the distal part of the sheath of the little finger to extend to the sheath of the thumb. Pus under tension in these bursas will rupture into the retroflexor space, an area between the pronator quadratus and the flexor tendons, and from here may extend up the forearm.

Fortunately, acute suppurative tenosynovitis is relatively uncommon when compared with other hand infections. It is usually secondary to puncture wounds, tooth wounds, or neglected infections in the fingers. It seldom occurs after injuries, even though the sheath is opened and the wound later becomes infected.

Early diagnosis and treatment of infection of the tendon sheath is of prime importance in order to prevent necrosis of the tendon and extension, both of which usually occur in neglected cases (29). The demonstration of a wound of entrance may be helpful, but is not essential, for diagnosis. The classical symptoms are semiflexion of the involved finger, diffuse uniform swelling, tenderness along the sheath, and pain on extension (Fig. 22). There is moderate systemic reaction with elevation of temperature. The diagnosis is sometimes difficult and may be confused with subfascial infections of the digits. Almost any infection of the finger will cause pain on extension and care must be taken to immobilize the middle and proximal phalanges while extending the distal phalanx to avoid stretching the soft tissues. Tenderness along the sheath is particularly significant,

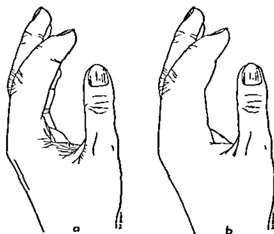

Fig. 22. Acute tenosynovitis of the index finger. a, early stage, showing merely the slight flexion and local swelling; this is the stage during which incision and drainage may be expected to result in complete return of function; b, later stage, showing extension of infection with suppuration and rupture outside the sheath. The tendon is probably necrotic at this stage and severe disability may result even if the infection is controlled.

entering the flexor tendon, which is inserted at the base of the phalanx, the knife should never reach the fold of the first joint. A similar incision may be made on the opposite side to ensure adequate drainage, but is not carried around the tip of the finger, the so-called "fish-mouth incision." This will produce a tender, sensitive scar. Chemotherapy, if started early, may obviate the need for operation.

4. Web-space Infection. The pus lies in the interdigital spaces of the web directly beneath the palmar fascia. The infection frequently begins as an infected callus, with a subcuticular abscess extending through the fascia to produce an abscess in the loose areolar tissue of the web. From here, the pus spreads quickly to the dorsal subcutaneous space. The web-space infection is also called a *collar-button abscess* because of the two pockets connected by a narrow channel.

The distal portion of the palm is tender

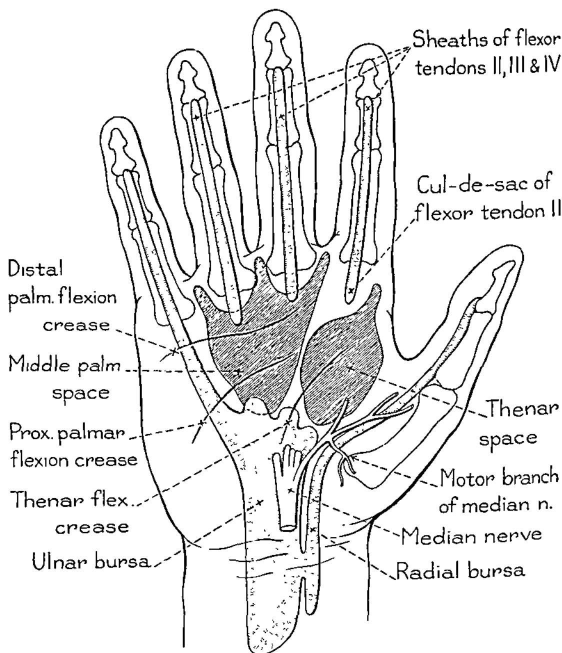

Fig. 21. The various spaces and tendon sheaths of the hand Note the relationship of the motor branch of the median nerve to the sheath of the flexor pollicis longus. (After Requarth in S. Clin. North America.)

Fig. 25. A neglected and inadequately treated case of acute tenosynovitis. The infection apparently ruptured into the subcutaneous tissue without extending into the fascial spaces; this abscess had been opened by a small incision. The necrotic tendon is visible. Healing was prolonged and resulted in a complete loss of flexion in the middle finger.

dle, and ring finger sheaths are opened through incisions placed along their lateral aspects. A second incision is always made transversely in the palm to drain the cul-de-sac. The incision for sheath infections of the thumb and little finger must avoid the motor branch of the median nerve, which lies directly in the path of the incision. The retroflexor space is always drained in radial and ulnar bursa infections, even though there is no evidence of pus in that region. This space is easily entered through a short incision just volar to the flat surface of the radius at the wrist (Fig. 24). A frequent complication of tenosynovitis is necrosis of the tendon with subsequent prolonged drainage (Fig. 25). Necrotic tendon acts as a foreign body the same as bone sequestrum and should be removed as soon as it is known to be necrotic.

6. Middle Palmar-Space Abscess. This space lies deep in the palm on the metacarpal bones and interosseous muscles, bounded on its radial aspect by the middle palmar septum, which extends from the center of the third metacarpal bone to the palmar aponeurosis, and on its ulnar side by the hypothenar muscles (Fig. 26). The flexor tendons of the third, fourth, and fifth fingers cover the palmar space. Distally, it is divided into many small compartments by multiple fibrous septa extending vertically downward from the palmar aponeurosis. Primary infection of the midpalmar space is rare except after a human bite wound of the dorsum which extends down the lumbrical canal into the palm. Neglected sheath infections of the third and fourth fingers occasionally rupture into this space.

Early, there are few signs except for tenderness in the palm and some pain on extention of the fingers. Later, the palmar concavity is obliterated and the palm assumes a thick, flat contour with marked edema of the dorsum. The palm is exquisitely tender with the fingers held semiflexed. Since the tendons of the middle, ring, and little fingers overlie the abscess, there is marked pain when these are extended.

The middle palmar space is drained through a transverse incision in the distal part of the palm parallel to the distal palmar flexion crease. The operation should be done in a bloodless field with care to avoid injury to the digital nerves and flexor tendons, which cross the line of incision at right angles.

7. Thenar-Space Abscess. The thenar space is separated from the middle palmar space by the same fibrous septum extending

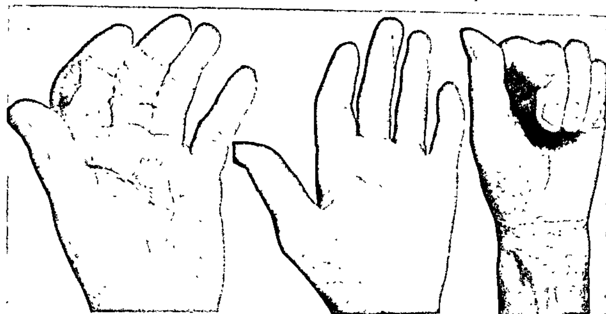

Fig. 23. Acute tenosynovitis of index finger. Left, five days after incision and drainage; middle and right, healed, showing degree of function lost. Emergency drainage of sheath infections is necessary to prevent loss of function.

especially in thumb and little finger infections. Slight redness may be present, but the infection *must not be mistaken for acute lymphangitis,* which, of course, requires nonoperative treatment, whereas acute tenosynovitis requires prompt incision.

Immediate drainage is imperative to avoid damage to tendon (Fig. 23). The index, mid-

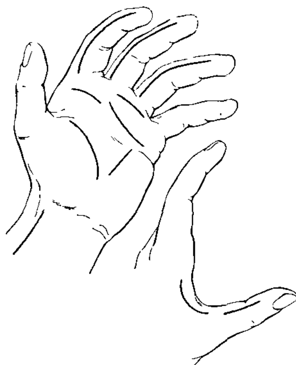

Fig. 24. Types of incisions for space infections of the hand. Lines of incisions for draining web space infections, sheath infections, middle palmar, thenar, and retroflexor spaces. Incisions must not cross flexion creases nor be in the mid-line. They must not damage important structures nor lead into uninfected areas. (After Requarth in S. Clin. North America.)

Fig. 27. A partly disabled hand resulting from extensive and multiple infections. The infection started with a bruise which the patient, a diabetic, opened *with a pin; an infection developed, which was lanced* three days later by her doctor. The thenar and mid-palmar spaces, as well as several dorsal abscesses had to be incised and drained before healing was complete. Present condition, one and a half years later, represents only a partial return of function.

(*b*) Tenosynovitis of the index finger is limited by the termination of the sheath, but ruptures (especially in neglected cases) readily *into the thenar space, which is in close relation* to the tendon sheath of the index finger.

(*c*) Tenosynovitis of the middle and ring fingers is likewise limited by the termination of the tendon sheaths, but ruptures readily *into the midpalmar space. Occasionally,* infection in the tendon sheath of the ring finger *may rupture into the ulnar bursa.*

(*d*) Tenosynovitis of the little finger extends readily into the ulnar bursa, and thence under the annular ligament into the forearm.

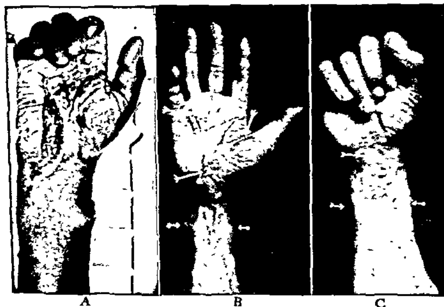

Fig. 28. Incision into the ulnar and radial bursa extending above the wrist. A, photograph *after incisions;* B, and C, results obtained two and a half months after treatment. (From Kanavel. Infections of the Hand, Lea & Febiger.)

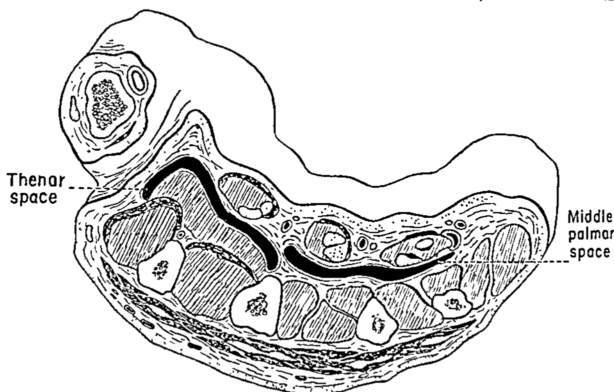

Fig. 26. Cross section through palm showing relationship of mid-palmar septum to palmar and thenar spaces.

from the middle metacarpal bone to the palmar fascia. It lies on the abductor pollicis muscle and is covered by the flexor tendon of the index finger. Thenar-space abscess is also rare. The chief sources of infection are puncture wounds of the radial portion of the palm or rupture of a neglected sheath infection of the index or middle finger.

The characteristic feature of thenar-space abscess is the balloonlike swelling of the thenar region, which holds the thumb in extreme abduction. The index finger is semiflexed and attempts to extend it cause pain. As in other major infections of the hand, there is marked edema of the dorsum. The diagnosis is not easy, because cellulitis in this region produces a similar picture although without abduction of the thumb.

Thenar space is best approached through an incision which parallels the edge of the thenar web. The first interosseous muscle is retracted and a forceps thrust through the fibers of the abductor pollicis muscle.

Infections of both the middle palmar and thenar spaces are now uncommon possibly because of chemotherapy. However, they may still occur when such therapy has been neglected or proves ineffective for reasons already discussed (Fig. 27).

8. Infections of the Radial and Ulnar Bursas. As already indicated, this type of infection is secondary to involvement of the tendon sheath of the thumb and little finger respectively, or of the palmar spaces. Though rarely involved primarily, it tends to spread rapidly up into the forearm and to produce necrosis of the flexor tendons. Diagnosis is helped by finding local tenderness and swelling. Flexion and extension of the respective digits will be limited sharply because of pain. Fever is quite constant as in fascial-space infection. Early incision is indicated (Fig. 28). Even if necrosis of the tendon is prevented by early incision, there may still be disability because of the adhesions between the tendon and its sheath.

Summary of Methods of Extension. The mode and direction of extension of infection in the various spaces of the hand may be summarized as follows (modified from Homans):

(*a*) Tenosynovitis of the thumb spreads readily to the radial bursa, and thence under the annular ligament into the forearm.

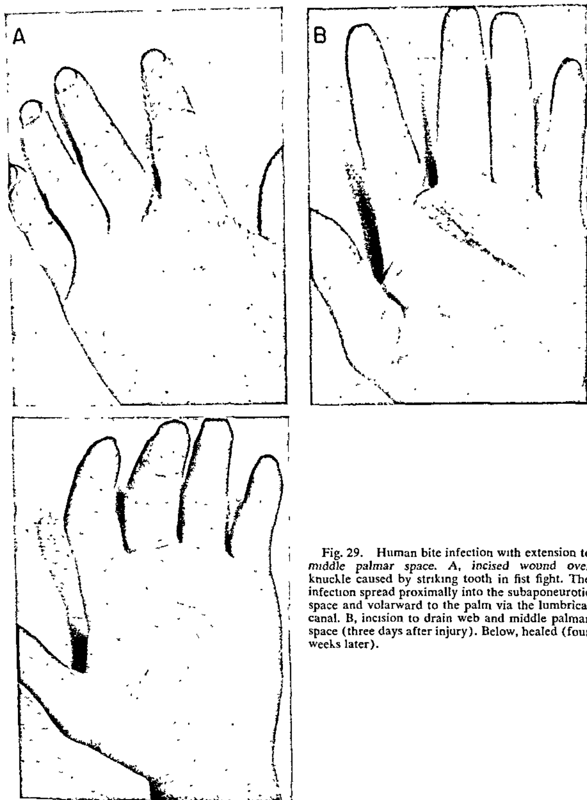

Fig. 29. Human bite infection with extension to *middle palmar space. A, incised wound over* knuckle caused by striking tooth in fist fight. The infection spread proximally into the subaponeurotic space and volarward to the palm via the lumbrical canal. B, incision to drain web and middle palmar space (three days after injury). Below, healed (four weeks later).

(*e*) An abscess in the thenar space may rupture into the radial bursa or midpalmar space; likewise, an abscess in the midpalmar space may rupture into the thenar space or ulnar bursa; *an abscess in the radial and ulnar* bursa may rupture into the thenar and midpalmar space respectively. Extension into the forearm under the annular ligament usually arises from the ulnar or radial bursas, but apparently may occasionally extend from the midpalmar space. In either case such extension should be detected when present.

Human Bite Infections of the Hand. These injuries deserve special mention because they present several unusual features. Experience has shown that wounds contaminated with human mouth organisms are very dangerous and produce the most destructive infections seen in the hand (30, 31). The functional disturbances which result are most serious *and often cannot be avoided in spite of careful* management. Although there is a wide variety of organisms in the mouth, the destructive part of the infection is caused by the spirochete and the fusiform bacillus growing in symbiosis under anaerobic conditions. They are not always demonstrable on smears and cultures but darkfield examination of a wet specimen will reveal their presence. The streptococcus, staphylococcus, and *E. coli* are often recovered from the wound. *Because of the bacterial flora of the human* mouth, these wounds are much more serious than the tooth wounds of an animal.

The majority of bite wounds occur over the knuckles, the result of a fist fight (Fig. 29). Penetrating wounds of the subcutaneous and subaponeurotic spaces are ideal for anaerobic infections, particularly those on the dorsum of the hand. With the fist clenched, a tooth wound over the metacarpophalangeal joint can easily injure the extensor tendon, open the joint, *and even damage the bone.* When the fingers are extended, the wound of entry glides proximalward with the aponeurosis and carries organisms into a closed area. Conditions are then ideal for anaerobic growth. The onset of a bite infection is usually rapid and within 24 hours the area is red and swollen. A grayish, watery, foul discharge appears first. Pain is prominent and aggravated by the slightest degree of motion; the temperature is elevated. Seemingly trivial wounds may be extremely serious. As the infection progresses, gangrene of the superficial tissues ensues and a large amount of *thick, putrid* pus exudes from the wound. Tenderness and pain in the palm indicate infection of the middle palmar space.

TREATMENT. The treatment consists in immediate cleansing with soap and water and immobilization on a splint. Under no circumstances should these wounds be closed, even though it is a temptation to suture what may *appear to be a clean laceration.*

After proper cleansing, the hand is put on a splint in the position of function and warm, moist dressings are applied. Massive doses of penicillin may abort the infection unless the metacarpophalangeal joint has been entered. In such cases suppurative arthritis, osteomyelitis, and ankylosis usually follow.

A most important phase of treatment is the detection of extension. At first, this occurs laterally in the soft, subcutaneous tissue of the dorsum but the pus soon moves *distally* along the side of the finger to the lumbrical canal and palm. The first sign of midpalmar-space infection is an indication for incision and drainage of this space. It is most important that this be done early to avoid destruction of the flexor tendons.

Operations on Hand Infections. Unlike the *simple operation for opening* furuncles or simple abscesses elsewhere, the surgical treatment of serious hand infections is often a procedure requiring the utmost of special judgment and skill. With the exception of paronychia and superficial abscesses, all hand infections must be treated with the greatest respect and care. Unless one is prepared to treat these patients adequately, it is far better to call in someone who can.

The decision as to the proper time for in*cision and drainage* is of great importance. Incision into an area of acute cellulitis or lymphangitis is a surgical error; on the other hand, early incision of a *felon or acute* tenosynovitis is essential for rapid and complete restoration of function. Diagnosis of the type and exact location of the infection *is* obviously a prime necessity. Frequent examinations may help, but the judgment and experience of the surgeon often spell the difference

3. *Gangrene* of the finger or entire hand is practically always due to special infections. Gas bacillus invasion is not the only one. Human bites, because they are symbiotic infections, may increase virulence to the point of producing gangrene.

4. The *disabled hand* is a term used to describe the stiff, atrophic, useless hand which follows severe or inadequately treated infections. It is particularly prone to develop after acute tenosynovitis and infections of the bursal and palmar spaces. The tremendous scarring with adhesions between the tendons, their sheaths, and adjacent tissues, is responsible in a large measure for the deformity and lack of mobility. To bring such a hand back to useful function presents a difficult therapeutic problem. Such disability can be prevented in a great measure by maintaining the hand in the position of function during immobilization. This seems a difficult lesson for physicians to learn, and the "claw hand" with metacarpophalangeal joints stiff in extension and phalanges pulled into flexion, is still a common sequela after infection or injury. Physiotherapy is helpful to a limited extent. The intelligent application of continuous traction splints will often correct deformities in a few weeks time (33). Most important is the attitude of the patient which must be one of willing cooperation and constant personal effort to increase the range of function.

between a correct and an incorrect diagnosis and treatment. While chemotherapy may obviate the need for operation, as already mentioned, it may also complicate the decision as to its timing.

In operating upon hand infections a general anesthesia (gas or pentothal sodium) should be used. Blockage of the digital nerve at the base of the finger with large quantities of procaine and epinephrine or use of procaine in conjunction with a rubber-band tourniquet can cause gangrene of the digit (32). By using a general anesthesia all pain is avoided, and the surgeon may carefully make his incision, explore the abscess or space without haste, and make whatever counter or extended incisions are necessary.

Intelligent treatment requires an accurate knowledge of the anatomy of the hand. One must have consideration for the many small structures and understand their close anatomic relationships in order to place incisions exactly. The size and location of the incision or incisions depends on the type of infection. On the palmar surface of the hand, transverse incision along flexion creases should be used wherever possible(Fig. 24). Incisions must be sufficiently long to drain the abscess adequately. On the other hand, it is essential that extension of the infections by incising uninvolved structures or areas of active cellulitis be avoided. Counter incisions may occasionally be indicated, as in a felon, but through-and-through drains cause harmful pressure on nerves and tendons and should not be used. A drain is used to hold the skin apart in order that pus may escape; it should not be packed into the wound to act as a stopper. Drains are usually unnecessary after 48 hours and should not be reinserted. Finally, it should be re-emphasized that all surgery on *the upper extremity be done in a bloodless* field.

A perfect functional result cannot be achieved without good *postoperative care* which includes adequate chemotherapeutic coverage. Warm, moist sterile dressings are used for a few days only, because if used longer the skin becomes macerated and loses its resistance to bacterial invasion. After discontinuing moist dressings, the hand should be soaked twice daily in warm sterile water, dressed with dry gauze, and immobilized on a splint. Dressings should be changed with strict observance of asepsis, lest other contaminants be added to the already infected wound. Specifically, one should not use his fingers but handle dressings with forceps; a mask should cover the nose and mouth. Injured tissues must be immobilized to promote healing and decrease pain; proper splinting is therefore a major factor in successful treatment. The hand is splinted with the wrist slightly extended, thumb abducted, and the metacarpophalangeal joints flexed to 90 degrees (position of function). As soon as the infection subsides, active motion should be started and each joint put through a full range of motion once a day. During rehabilitation, much depends on the cooperation of the patient to increase active motion of the joints as soon as subsidence of pain permits.

Complications of Hand Infections. Lymphangitis, lymphadenitis, and septicemia frequently complicate infections of the hand as discussed earlier in this chapter. The other complications, perhaps less common but nevertheless serious, are as follows: osteomyelitis, arthritis, gangrene, and the disabled hand. Many of these complications are now relatively rare thanks to modern chemotherapy, especially when started early in the stage of invasion.

1. *Osteomyelitis* is generally due to neglected or inadequate treatment. Its development in a felon has already been described. It also occurs in the metacarpal bones after human bite and neglected space infections. Persistent swelling or drainage for more than two or three weeks suggests osteomyelitis which can be verified radiologically.

2. Suppurative *arthritis* is an infrequent complication unless a joint has been infected *primarily at the time of the injury*, as in human bite wounds. Diagnosis is not difficult because even the slightest movement of the joint causes exquisite pain. There may be a grating sensation elicited in the joint upon movement of the finger. There may also be abnormal mobility of the digit due to destruction of the supporting ligaments. Early incision is indicated to prevent, as much as possible, the destruction of tissue (especially the cartilage).

are dependent upon the degree to which the blood supply is impaired and upon the existence of certain types of infection, such as that produced by the gas bacillus. The following conditions are capable, either alone or in combination, of leading to such changes to the degree that amputation will be necessary.

Trauma. Extensive trauma may of itself result in destruction of so much tissue as to destroy the blood supply to the distal portion. However, when only a portion of the limb is severed, amputation should be withheld, particularly if the bone is not fractured. So often, extremities, which at first appeared doomed to gangrene, recover with loss perhaps of only toes or portions of them. Naturally, if infection develops, the indication for amputation is greatly increased. Fortunately, great strides in combating the infection have been made, and many limbs which might otherwise be sacrificed can now be saved. The measures which minimize the incidence of infection in wounds have been discussed in Chapter 14. Important ones are proper débridement, immobilization, antibiotic therapy, adequate irrigation, and zinc peroxide. Gas gangrene antitoxin is also used, but its value is uncertain. The incidence of gangrene (and amputation) of injury has also been sharply reduced by modern methods of arterial replacement (see Ch. 25). The incidence of amputation in war wounds involving the extremities is apt to be much higher than in injuries sustained in civil life, partly because of more severe trauma and the presence of foreign bodies (shell fragments, dirt, clothing, and so forth), but particularly because infection is much more likely, due to the fact that many hours frequently elapse between injury and therapy. For details of amputations under war conditions see Chapter 42.

Arteriosclerosis. Amputation performed because of arteriosclerotic gangrene is comparatively frequent and generally is limited to patients in the latter decades of life. The gangrene may be extensive, involving the entire foot and part of the leg. Fortunately, it is usually of the dry type with a minimum amount of infection, thereby justifying delay in regard to the time of operation. Such delay is frequently advisable because spontaneous demarcation of the extent of gangrene usually occurs, with a consequent preservation of a maximum amount of tissue. On the other hand, conservative therapy is often inadvisable because of increased disability, expense of prolonged hospitalization, and particularly because of the danger of infection. When infection develops, immediate amputation may be indicated because infection is more difficult to control in ischemic tissue. In this disease also, the use of arterial grafts has, in some cases, changed the older concepts and indications for amputation.

Diabetic Gangrene. The gangrenous process occurring in diabetes is usually not very extensive but is directly secondary to occlusive arteriosclerotic changes which are so common in diabetes. The gangrene is usually associated with infection, thereby making amputation urgent. If the process is primarily of infectious origin with little or no gangrene, conservative therapy including incision and drainage will usually suffice. As discussed in Chapter 19, more effective antibiotics have allowed us to be much less radical with amputations in diabetics.

Buerger's Disease. Gangrene in Buerger's disease is relatively slight, usually limited to the tips of the toes, is superficial, and is not commonly associated with severe infection. For these reasons, amputation will rarely be necessary and usually need be no more extensive than removal of a toe or part of a finger.

Infection. Amputation for infection is most commonly indicated when produced by the *gas producing organisms.* When the gangrene is beyond the limits of local care, amputation will be urgent and should be performed high, particularly if there is evidence of arterial obstruction; under such circumstances, the operation should be of the guillotine type. Other measures are also used, as discussed later in this chapter. It should be emphasized, however, that with the aid of modern chemotherapy, amputations will rarely be necessary except in patients who have been badly neglected or, on occasions, when the blood supply is badly damaged by trauma or by one of the vascular diseases such as arteriosclerosis.

Other types of infections may act as indications for amputation but practically only when significant arterial obstruction is also

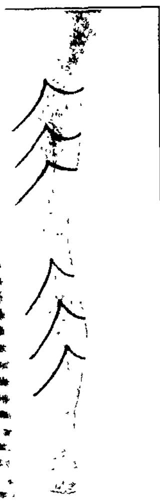
AMPUTATIONS

Indications for Amputation
The Extent of Amputation
Amputations in Children
Operative Considerations



Decades ago, before the advent of asepsis, amputation was perhaps the most frequently performed operation; actually, it was performed in the majority of open fractures and massive soft tissue injuries of the extremities because such wounds were so often followed by septicemia and death. Unfortunately, the operation itself was also apt to be followed by the same train of events. An eminent writer in London about 1782 said that amputation "is an operation terrible to bear, horrid to see, and must leave the person on whom it has been performed in a mutilated, imperfect state." A surgeon who observed personally 46 amputations stated that of these, ten died, one of locked (sic) jaw, two of hemorrhage, four of hectic fever, and three from spreading gangrene. In 18, severe hemorrhage occurred and all suffered from violent "symptomatic" fever. Of those who survived many had painful stumps or wounds which failed to heal, probably because of osteomyelitis (1). The absence of anesthesia made the actual performance of the amputation a terrifying affair, and many are the weird tales of the slashing brutal methods incident to the operation. Time became the most important factor in the technic; the reputation of the surgeon depended almost entirely on the number of seconds he needed to dismember the affected limb. It was a shameful reputation for a surgeon to require as much as three or four minutes for the operation. The junior medical students of those days as they watched these performances were admonished by their serious classmates, "Don't blink your eyes, you will miss the operation."

This tradition of speed has unfortunately been handed down far too literally even to the present time. Many surgeons still use the time factor as a measuring rod of surgical excellence because they fail to realize that, in the average amputation at the present time, other factors are of equal or greater significance. Thus, far less harm is sustained by the patient if the procedure is done with proper care and respect for tissues than if performed in seven or eight minutes in a dramatic but needlessly traumatic fashion, necessitating mass ligatures and gross mauling of tissues. Needless to say, the operating time should be reduced to a minimum but not below a limit which will permit careful work. The blind worship of speed alone is an anachronism in the present century, and, when cultivated, deserves severe censure.

During the four year period of World War II, approximately 18,000 American service men lost limbs as a result of injuries. However, as Kessler (2) notes, "during the same period 120,000 American civilians lost limbs as a result of accidental injuries." This latter figure does not include amputations for arteriosclerotic gangrene and other vascular diseases which are increasing because of the gradually increasing life span.

INDICATIONS FOR AMPUTATION

In general, amputation is indicated 1. to save life (from the threat of infection and gangrene); 2. to combat incurable disability; and 3. to restore the individual to more useful activity despite the loss of limb (3). Based on specific surgical diseases, the two major factors determining the necessity of amputation

present. This point should be kept in mind, *lest amputations be performed needlessly* when incision and drainage together with other conservative measures will suffice. As already stated, any type of infection superimposed upon an existing gangrene may make amputation urgent. It is important to emphasize the necessity of making cultures (and especially stained smears) on all such lesions so that the etiologic organism or organisms may be identified and treatment varied accordingly. If a gas bacillus is found in the lesion before amputation, even with no clinical manifestations, the wound should be left wide open. If the material for bacterial examination is obtained for the first time at the operating table, the information may still be of great aid. Thus, even if a gas bacillus is first identified 24 to 48 hours after operation, the wound, if closed, should be opened widely, intensive chemotherapy instigated, and zinc peroxide applied; antitoxin may be advisable even though there is no proof that it is effective.

The mere presence of gas in the tissue is not at all proof that a gas bacillus infection is present; moreover, occasionally gas is produced by nonpathogenic organisms. In true gas gangrene with the proper use of antibiotics we are often able to excise certain muscle groups and avoid amputation.

Occasionally, amputation will be indicated for tuberculous or pyogenic osteomyelitis of the tarsal bones of the foot because either type rarely heals and usually is so painful as to be totally disabling.

Embolism. When an embolus lodges in a major accessible artery, the clot should be removed, with few exceptions, if the patient is seen within eight to ten hours after the embolism occurs. In late cases, or in unsuccessful embolectomy, amputation may be necessary. However, since infection is usually absent in these cases, amputation may be avoided by vein or artery grafts or delayed in order to wait for the development of a line of demarcation, thereby saving a maximum portion of the extremity. If the patient is young, delay is advisable because it permits the collateral circulation to reach its maximum. Not infrequently, the patient may then suffer only the loss of perhaps not more than a part of one or two digits, whereas the loss of a major part of the extremity might have seemed imminent earlier in the disease.

Of the major vessels to the extremities, obstruction of the common iliac and popliteal arteries is most apt to lead to gangrene. Embolism to the major arteries of the upper extremity results in such limited gangrene that amputation is rarely indicated, although embolectomy may be advisable to minimize the effects (see also Chapter 25).

Malignant Neoplasms. Sarcoma of bone is the most important neoplasm for which amputation is sometimes indicated, although there is considerable dispute as to whether amputation is advisable in certain types of bone tumors as discussed elsewhere. Occasionally, neglected squamous cell carcinomas (most common in the upper extremity) may invade so deeply that amputation is justified.

Deformity. Amputation is occasionally indicated for deformity, but usually only when function is completely lost and the deformed, useless member interferes with movement of the remainder of the extremity. For example, a severe injury or infection in a finger might result in a total loss of function. If the patient makes his living in a vocation or trade requiring deft movements of the fingers, the deformed finger might be a tremendous handicap in carrying out his duties; amputation of the deformed digit will frequently increase his efficiency. Injuries of the foot, with preservation of a part of the foot (for example, the Pirogoff and Chopart amputation) with or without deformity, may result in a painful or inefficient stump as far as function with a prosthesis is concerned; amputation at a higher level may be the procedure of choice in such instances. In all such cases, the decision is based largely on the need or possibility of reducing disability, rarely on cosmetic considerations.

Optimum Levels. The surgeon does not always have the opportunity of performing the amputation at the ideal level as a primary operation. This is particularly true in serious infections in very ill patients; in such a case, a guillotine type of amputation may be necessary followed later by a planned reamputation at a higher level when the infection has subsided. Likewise, in a seriously injured pa-

Fig. 1. Lines of Skin incisions for leg and thigh amputations. (Redrawn from Orr. Modern Methods of Amputations, C. V. Mosby.)

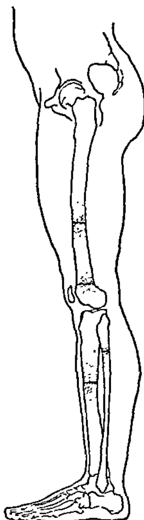

Fig. 2. The shaded areas of the bones represent preferential locations for amputation; the optimum level is indicated by the most dense shading.

tient, an emergency amputation may have to be performed through injured tissue, even though it is obvious that reamputation at a higher level will have to be performed later. With these exceptions, amputation should be carried out in practically all cases at optimum levels as discussed below.

In the *lower extremity* (Figs. 1, 2), amputations present entirely different problems from those in the arm. If the patient is to walk without crutches, an artificial limb of some type is obviously necessary. For this reason, close cooperation is essential between the artificial limb makers and surgeons. In general, two types of limbs are made. In one, the weight of the body is transmitted to the end of the stump, which thus may be called an end-weight-bearing stump. In the other type, a conical bucket is made into which the stump fits so that weight is transmitted largely to the sides of the stump and bony prominence. In amputations below the knee, weight is transmitted to the tibial tuberosities, tibial tubercle, and fibular head (Fig. 3A). In *above the knee* amputations, which are not end-weight-bearing, weight is transmitted to the ischial tuberosity (Fig. 3B and 4). The end-weight-bearing stumps, of which there are two, the Syme at the ankle and the Gritti-Stokes at the knee, are superior to other lower extremity stumps, and, when it is possible to produce either, it is the method of choice. They have greater durability than other stumps, and an individual with either of these

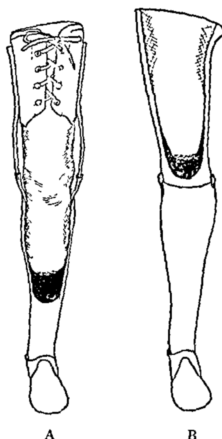

Fig. 3. Longitudinal section of the "buckets" of artificial limbs. A, weight-bearing on the sides of the leg stump. Occasionally it is necessary to remove the entire fibula before the limb can be worn with comfort; B, the soft tissues of the thigh serve admirably to sustain the weight of the body. Many artificial limbs are designed so that considerable weight is borne on the ischial spine but there is a growing tendency to have the weight borne entirely on the sides of the stump.

Fig. 4. Simplified type of amputation. Note absence (Courtesy, Hanger Artificial

stumps can acquire a gait superior to that possible with amputations at other sites.

Disarticulation through the knee is an excellent and nonshocking emergency open amputation when there is no chance of preserving the knee joint. It permits an excellent secondary revision. It is also an excellent type of definitive operation, as the bulbosity produced by the condyles and patella tends to stabilize the prosthesis and it is an end-weight-bearing durable stump (4). Its great disadvantage is the fact that few prosthesis makers will take the pains to properly fit it with an artificial leg.

Below the knee, the ideal length for a stump is 5 to 7 inches, depending on the height of the individual. The taller the individual, the nearer the stump length should approach 7 inches. Howe emphasized that a stump is preferable to a knee joi because, with skillful pros patient's own knee joint utilized even with such a chief advantages of this le that the stump can be fitt tients can learn to walk with One serious disadvantage tient cannot stand very long cause weight-bearing is limit tions at the *ankle*, the Sym above the articular cartilage c serving the flare of the tibia the lower ligamentous anchora to the tibia), being end-wei extremely serviceable. tion, the individual needs of the patient must obviously be considered. Amputation of toes or the distal portion of the phalanges will, of course, leave a serviceable stump and should produce very little disability. Of the amputations through the *foot*, the transmetatarsal (5) is the only satisfactory one. Any amputation in the foot proximal to the transmetatarsal area is not under balanced muscle control and often assumes a fixed deformity and develops painful callosities and bursae. The Pirogoff, Lisfranc, Sedillot, and many other eponymic amputations in the foot are only of historical interest and should not be used. If a balanced transmetatarsal amputation cannot be obtained, an individual is better off with a Syme amputation. In amputations above this level, the minimal length of the stump, for functional value in fitting the prosthesis, is 2.5 inches. Many of the mechanisms involved in the prosthesis for amputations in the lower extremity are illustrated in Fig. 5.

Amputations through the *arm* should leave a stump as long as possible, particularly in the upper portion. Although prostheses can be fitted to stumps only 2 or 3 inches long, they are of little functional value and are worn chiefly for cosmetic purposes, i.e., to fill out the shirt or coat sleeve. There is little difference, from the standpoint of efficiency of the stump, between an amputation just above the condyles and a disarticulation at the elbow. In the latter, the prosthesis can be held more securely with a minimum amount of apparatus, but the artificial joint will have to be put on the outside, making the limb more cumbersome.

In the *forearm*, the junction of lower and middle thirds has been considered the ideal site; however, with the development of newer prostheses which incorporate pronation and supination movements, it is wise to preserve as much as possible (Fig. 6). Some long forearm stumps will be cold and develop circulatory changes and ulceration. In the *hand*, as much length and tissue are preserved as pos-

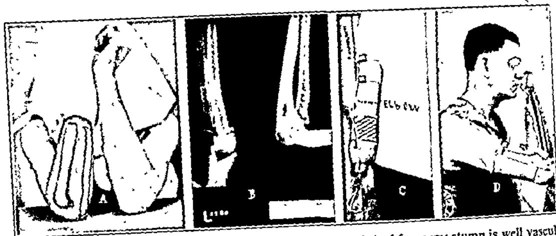

Fig. 6. Ideal forearm stump, junction of middle and lower third of forearm; stump is well vascularized and provides adequate lever for hard use of prosthesis. A, photograph. B, roentgenogram. sible. One functioning finger is usually of more service than an artificial limb, although it is of course more desirable to have two fingers so that the function associated with opposition may be maintained. The thumb is usually the most important, since, even in the absence of all the other fingers, objects may be grasped between the thumb and stump of the hand.

THE EXTENT OF AMPUTATION

There is general agreement as to the optimum level for amputation in each segment of the upper and lower extremity as just described. Despite this, the decision must be made as to how much of the limb needs to be sacrificed; e.g., shall the lower extremity be removed at the thigh or leg? This problem is usually due to uncertainty as to the status of the blood supply to the lower leg and is complicated also by the presence of infection and gangrene. In certain specific cases (particularly in diabetic gangrene and infection), the amputation should be done through the thigh. In doubtful cases, valuable information as to the status of the circulation may be gained by first making exploratory incisions through the leg to determine the actual condition of the blood vessels and to determine the level of adequate blood supply. Numerous tests are available which serve the same purpose without exploratory incision. They may be described as follows.

Temperature of the Skin. A valuable, and one of the simplest tests of circulatory efficiency to the extremity is the determination of skin temperature, and particularly of a line of temperature demarcation. This may be done by thermocouple or thermometer, but the hand is fairly accurate in determining differences between warm and cool areas over the extremity. A thermocouple in a needle has the advantage of obtaining measurements of temperature deep within the muscle. Frequently the gradation from warm to cold will be abrupt, thus indicating sharply the site where serious arterial deficiency begins; usually it is fairly gradual. The borderline can usually be made sharper by exposing the patient's extremities for 15 or 20 minutes to room temperature and then covering them with warm blankets for a similar period. Upon exposure, the area with deficient blood supply will become quite cold and, when covered, will fail to become warm with the rest of the extremity. These features will be more noticeable by contrast if the circulation of the other extremity is reasonably normal. With few exceptions, the amputation should not be performed below the line of temperature demarcation.

Color. Changes in the normal color of the skin may be of considerable aid in determining the status of the circulation and thus the appropriate level of amputation. Although the skin of many patients is pale over the entire body, the area deficient in arterial supply will usually have a cadaveric pallor. Any

doubt about a true deficiency pallor can be cleared to some extent by pressing the patient's skin firmly with the examining finger tip. If the blood supply is efficient, the pallor produced by the pressure will be replaced by the normal color in two or three seconds; if the blood supply is deficient, the color may not return for many seconds. Upon elevation of the extremity, if arterial deficiency exists, the foot will become extremely pale and, upon dependency, will become red or purplish. If this deep blush extends very far above the foot, amputation below the knee will rarely be sufficient. The skin over the involved extremity is usually atrophic and shiny. *The Moskowicz test, based upon color* change following application of a rubber tourniquet, should not be carried out on arteriosclerotic patients because of the danger of injury to the sclerotic vessel walls.

State of Major Arteries. Many of the tests devised to aid in determination of the optimum level of amputation are concerned primarily with estimating the extent and efficiency of collateral vessels, since these may be more accurate in determining healing power than the presence or absence of pulsations of a major artery. It is, nevertheless, important to palpate for the dorsalis pedis and posterior tibial pulse; extensive gangrene will not be apt to develop if both pulses are present. The presence or absence of the two pulses would also be important in deciding upon the advisability of a conservative course of therapy in a diabetic infection with doubtful areas of early gangrene. The popliteal pulse is usually valuable in a negative way; e.g., amputation below the knee is seldom safe in the absence of a popliteal pulse. Additional data concerning the blood flow through the popliteal artery may be obtained by taking a blood pressure reading over the lower femoral region. Normally, it should be 15 or 20 mm. higher than the brachial pressure. If it is lower or no higher than the brachial, the circulation may be considered to be impaired and amputation below the knee inadequate. A roentgenogram of the leg will determine the amount of calcification in the wall of the major arteries and thereby furnish accessory data as to the vessels themselves. Additional roentgen studies immediately after the injection of diodrast into the vessel above the suspected lesion may reveal obstructive lesions and the condition of the arterial wall.

Histamine Flare Test. Suggested by Lewis, this test consists of the injection of 0.1 ml. of a 1:1000 solution of histamine in 0.5 per cent procaine intradermally at various levels on the extremity. With a normal circulation there will be a hyperemic flare surrounding the point of injection, constituting a positive reaction. A positive reaction indicates that primary healing of a skin flap should follow amputation at that level. A negative reaction, however, does not exclude the possibility that *healing will take place at that point.*

McClure–Aldrich Test. Intracutaneous injection of 0.2 ml. of 0.85 per cent saline at various levels may be of value. The wheal should disappear normally in 60 minutes; in the presence of abnormal circulation, particularly in the presence of edema, the wheal disappears more rapidly.

Freezing Test. To gain information regarding the circulation, Nyström (6) has suggested observing the reaction after freezing the skin by holding a cylinder of packed carbon dioxide snow on the skin for three seconds at various levels on the extremity. With a normal circulation, the area will thaw and become hyperemic in about two minutes. The blanching produced by pressure of the finger over the area returns to a hyperemic color in one or two seconds. If the arterial supply is inadequate, the return of the hyperemic color may be delayed 15 seconds or more.

Oscillometric Readings. Various types of oscillometers for recording the amount of pulsation (diffuse—not over the arterial trunk) at a given level are available. Many of them record very accurately the amount of pulsation at that point. By comparing these records with normal curves, an estimation of arterial damage may be made, except that it is not possible to ascertain the proportion of pulsation which is due to collateral flow. This latter feature constitutes the major criticism of the oscillometer, since the *number of collateral vessels and the rapidity of development of new ones are of vital importance in the indications for, and site of, amputation.*

AMPUTATIONS IN CHILDREN

Amputations are rarely required in children, but, occasionally, trauma and malignant tumors end in loss of a limb. Because these patients are growing, amputation requires special consideration and the utmost in careful judgment. For example, deformities may be sufficiently severe to justify amputation, yet operation should not be performed in early infancy because it will stop growth of the extremity, so vital to the fitting of a prosthesis later.

Certain principles of amputation in children may differ from those in adults (7). For example, amputation through the knee joint is greatly preferred to a supracondylar level in children, so that growth from the lower femoral epiphysis may be preserved. For the same reason, if at all possible, amputation should be performed through the malleoli of the lower leg rather than through the middle third. Under these two circumstances, the fitting of a prosthesis during childhood will be difficult, but, after growth is attained, reamputation can be performed and a good prosthesis fitted properly.

OPERATIVE CONSIDERATIONS

Immediate Preparation of Patient. Attention must first be directed to the presence of shock (especially after trauma), and treatment such as transfusions and intravenous saline or dextrose must be administered before amputation is performed. In badly crushed and contaminated extremities, tetanus and gas bacillus antitoxin, in doses at least double the usual prophylactic dose,* should be given, as well as prophylactic chemotherapy. In diabetic patients (see Ch. 19), acidosis should at least be corrected and the urine be made as nearly sugar-free as possible in the time available.

The night before operation (if this much time is available), the amputation site should be shaved and washed gently but thoroughly with soap and water and covered with a sterile towel. The next morning in the operating room, this cleansing should be repeated, and, after the skin is dried, the site should be prepared with iodine and alcohol or with cleansing detergents.

Anesthesia. Spinal anesthesia is satisfactory for many lower extremity amputations. If any degree of hypotension results, hemostasis is likely to be poor and postoperative hemorrhage of serious degree is likely to occur in the stump, unless the hypotension is corrected by vasoconstrictor drugs before closure to reveal bleeding. Spinal anesthesia should not be used in patients with impending shock from trauma. For amputation in the upper extremity, some type of inhalation agent (e.g., cyclopropane) is preferable. However, if a cardiac lesion exists, it may be desirable to use local anesthesia. A brachial block will be adequate for amputation through the forearm, but this requires skill and may fail. Local nerve block may be used for amputations of the toes or fingers but has the disadvantage of traumatizing tissue already having an impaired circulation.

Operative Principles. A *closed stump* has the advantages of rapid healing and good scar line and should be utilized when possible. Some surgeons prefer to close the wound around a small rubber tissue drain, but there is a growing tendency to either close the stump tightly or leave it entirely open.

The use of a tourniquet is highly desirable to obtain a bloodless field, but severe damage including nerve palsy may result with elastic rubber tubing. If there is room, a blood pressure cuff is much more desirable and less apt to injure nerves or blood vessels. In elderly people with arteriosclerosis, a rubber tubing type of tourniquet is actually unsafe. A tourniquet is poorly tolerated by the finger and should not be used, particularly since there is little need for it.

If it appears that a bilateral amputation will be required on the lower extremities, one knee should be preserved if possible because it is extremely difficult for the patient to learn to manipulate two artificial knee joints. Naturally, the surgeon should not allow this factor to influence his judgment when an amputation below the knee may be dangerous to life.

* The prophylactic dose of gas gangrene antitoxin contains 1,500 units tetanus antitoxin, 2,000 units perfringens antitoxin, and 2,000 units septicum antitoxin. However, there is not convincing evidence that gas gangrene antitoxin is very effective in prophylaxis. Large doses of penicillin may be more effective.

The *types of incisions* for the various sites may be summarized as follows: 1. long anterior and short posterior flaps for the thigh; 2. long posterior and short anterior flaps for the leg; 3. flaps of equal length for the forearm; 4. long palmar and short dorsal flaps for the hand and fingers; and 5. long plantar and short dorsal flaps for the foot and toes.

In general, the final skin flap should not be cut at the initial incision. Rather, the principle is followed of making large flaps which will eliminate the necessity of closing the skin with tension. Large flaps also lessen the danger of jeopardizing blood supply by undermining skin flaps if an error is made with the initial incision. Moreover it is always easy to cut redundant skin just before final closure. Since infection is so apt to develop in amputation stumps, the *utmost care and gentleness must be exercised in handling the tissues:* traction must be gentle, no mass ligation is permitted, and the minimum number of hemostatic forceps is applied.

Conservation of blood is extremely important since these patients are so often precarious surgical risks. The application of an Esmarch bandage from below upward would obviously conserve blood but is practically always *contraindicated* because of the tissue damage resulting therefrom. However, elevation of the limb before applying the tourniquet will result in conservation of considerable blood, particularly if a high thigh amputation is being done. Very frequently indeed, even the application of a tourniquet will be contraindicated because of the damage inflicted on arteriosclerotic vessels by the pressure of the tourniquet. In such cases, however, the need for a tourniquet will not be so acute.

There are numerous *points* in *technic* which can be applied to practically all amputations. The bone should be cut across far enough above the level of the skin so that the wound can be closed without tension. A circular incision through the periosteum is made around the bone, and the bone sawed through just distal to that line, thus minimizing splintering of the periosteum with subsequent spur formation. Removal of a cuff of periosteum from the end of the bone is not advisable (McKeever, 8). In amputation of the leg, it is essential that the fibula be cut off at least an inch shorter than the tibia. Because the fibula is commonly a source of discomfort in spite of proper care at operation, some surgeons prefer to remove it completely at the time of amputation, particularly in short stumps. It is not necessary in the function of the artificial limb. No muscle flaps should be interposed over the bone ends, although fascia may be used to cover the bone. During the dissection, care must be taken lest the various planes unnecessarily be separated from the skin, because of danger of destruction of blood supply to the skin with consequent gangrene and perhaps severe infection. Nerve trunks should be traced upward for a short distance so that, when cut, the end will be out of the wound; thus the danger of pressure on the neuroma at the stump end will be minimized. Injection of the nerve end with alcohol is not advised. Large nerves are ligated to prevent bleeding.

Individual Types of Operation. Detailed description of technic of the various amputations may be found elsewhere (8, 9, 10), however, the principles including their application and usefulness, will be discussed (see also Fig. 5).

Open Amputation. This is an extremely useful operation; because of its simplicity and rapidity of performance, it is often, indeed, a lifesaving procedure. It can be performed at any level on either the upper or lower extremity. It is particularly indicated when infection or edema is present in the limb, or when contamination in the crushed or injured portion of the limb is considerable. For this reason it is especially adaptable for military injuries in which closed amputation is contraindicated. Since it is assumed that another amputation will be necessary at a later date, the line of incision is made as far distal as feasible. However, it is surprising how often the stump heals so smoothly that a reamputation is unnecessary unless a shorter stump is desired. The term "guillotine" should be abandoned in favor of "open," since, as Kirk and McKeever (11) have emphasized, the cut stump should not be flat but concave. To achieve this, the skin is incised and allowed to retract before the fascia is incised. The superficial muscles are cut at a higher and

the deep muscles at a still higher level, thus permitting exposure of the bone so it can be transected at least several centimeters proximal to the skin incision. The periosteum is cleanly incised, but the bone is sawed across immediately distal to this level without removing a cuff of periosteum from the bone end; exposure of bone free from periosteum would encourage sequestration, since infection will develop in such a high percentage of cases for which this operation is chosen. The use of catgut is preferred to silk or cotton in an open amputation. No closing sutures are taken. Traction must be applied, by adhesive or other means, immediately after amputation to prevent retraction of the skin and soft tissues above the bone. The traction can be released to allow dressings as indicated. It must be maintained until the open wound has completely healed (12).

AMPUTATION THROUGH THE THIGH. When the amputation is performed in the middle third of the thigh or higher, an end-weight-bearing prosthesis cannot be used since most of the weight is borne by the ischium. The scar should be posterior and above the end of the bone. To achieve this location, a long anterior flap and a short posterior flap are cut. It is advisable to save as much stump as possible down to within a few inches of the knee. Therefore, the position of the scar can be ignored if more length can be obtained by some other incision. Up until recently, short amputations of the thigh could not be fitted with efficient artificial limbs, but, since the introduction of the hip control limb, fair action can be obtained with a 2- or 3-inch stump. The original type of artificial limb, which was held in place by shoulder straps, tends, with certain movements, to fall away from the stump when it is short. When a disarticulation at the *hip* is necessary, the modern pelvic socket type of prosthesis will be surprisingly satisfactory. All muscles except those of the buttock should be removed.

AMPUTATION NEAR THE KNEE. Amputations at this level are particularly adaptable to artificial limbs sustaining considerable weight, thereby lending stability to the prosthesis. The *Gritti–Stokes amputation* is performed at the knee joint; the lower end of the femur and posterior part of the patella are removed with the saw so that the patella can be rotated and approximated against the end of the femur. Since an end-weight-bearing stump is thus produced, the skin over the end of the bone should be the toughest available. Using a long anterior flap, the skin normally overlying the patella becomes the weight-bearing portion of the stump. The anterior half of the patella is anchored to the end of the femur, where it heals in place. This procedure has been modified by Callander (13), who makes long anterior and posterior flaps and saws across the lower end of the femur above the condyles just proximal to the abductor tubercle, removing the patella, so that the stump of the femur may fit into the tendinous patellar socket and thus allow weight-bearing. This amputation is becoming quite popular and can be fitted very satisfactorily with an artificial limb, utilizing considerable weight-bearing, the chief advantage of which is stabilization of the artificial limb.

AMPUTATION THROUGH THE LEG. As stated previously, optimum length of a leg stump is 5 to 7 inches. Weight is borne on the side of the head and under the tubercle of the tibia, against the conical shaped bucket of the prosthesis. For this reason, the patient can rarely stand all day on his feet because of skin irritation and pain at the site of the weight-bearing. The skin chafes and blisters, and hair follicle infections are common. However, the stump is easily fitted with a prosthesis, and the patient can learn to walk with very little limp. In women who do not need to be on their feet very long at a time, it is particularly adaptable because of the good cosmetic appearance. The fibula should be sectioned about an inch above the level of the tibia and the corners smoothed off well. Although many surgeons remove it entirely, its presence is helpful in rotating the prosthesis. Excision of the fibula is advisable, when possible, in short leg stumps because it yields a rounder and more conical stump. Amputations in the lower third of the leg are considered unsatisfactory by most surgeons because of poor circulation and increased sensitivity and by prosthesis makers because the long stump may actually interfere with the ankle mechanism. If not enough leg stump remains to preserve the optimum 6 inches of tibia, it

is still preferable to preserve a shorter length rather than do an amputation above the knee, because a stump of no more than 1 or 2 inches will aid greatly in controlling the prosthesis. In selected cases of peripheral vascular disease, a circular amputation 4 to 6 inches below the knee may avoid thigh amputation. The stump is closed with lateral flaps using deep sutures through skin, fascia, and muscle. Preliminary lumbar sympathectomy may be indicated in some cases.

AMPUTATION THROUGH THE FOOT. The only satisfactory amputations through the foot are the *transmetatarsal* and *metatarsophalangeal* procedures. The latter is much less applicable than the former. The *Lisfranc* and *Chopart* amputations are unsatisfactory because muscle balance of the stump is destroyed, with resultant deformity on many occasions. The principle of the *Pirogoff* amputation is satisfactory, but for success it is necessary that the resected portion of oscalcis and cut end of tibia unite; this union will not always take place satisfactorily. The *Syme* amputation is the most satisfactory amputation when a transmetatarsal amputation cannot be carried out. It results in an end-weight-bearing stump which will tolerate strenuous usage. To obtain a good Syme stump, this operation must be properly executed. The malleoli are not removed, but the tibia and fibula are sectioned not more than 1 cm. above the cartilaginous surface of the tibia, thus preserving the bulbous flare of the ankle and also the lower ligamentous anchorage of the fibula to the tibia. Amputation above the malleoli and above the inferior tibiofibular ligament is not a Syme amputation and results in an unsatisfactory stump. It is essential in the Syme amputation that the os calcis be removed subperiosteally so that the heel flap may firmly adhere to the lower end of the tibia. It is also necessary that the heel flap be accurately centered on the tibia. Failure to observe these details at operation and in postoperative care will result in a totally unsatisfactory stump, to which a prosthesis cannot be fitted. If the Syme amputation is not possible, it is then usually preferable to go several inches higher, leaving a stump of tibia equal to 6 or 7 inches.

AMPUTATION THROUGH THE SHOULDER. Many different types of skin flaps have been described for *amputation of the shoulder,* e.g., Kocher, Larrey, Dupuytren. A shoulder girdle amputation includes removal of the entire upper extremity with the scapula and most of the clavicle.

AMPUTATION THROUGH THE ARM AND FOREARM. The optimum levels and some of the other features of amputations in these regions have already been discussed. Anterior and posterior flaps of equal length are cut so that the scar will be on the end; the sides of the stump govern motion of the prostheses. Artificial limbs fitted to an arm stump are of little functional value, but are of great psychologic and cosmetic value. However, prostheses for the forearm are of considerable functional use (Fig. 6). The conventional type is equipped with a mechanical hand which is interchangeable with a utility hook; motions are controlled by straps from the opposite shoulder. With practice and training, accomplishments with these appliances for a forearm stump are astonishing (14, 15); the patient can readily learn to eat with both hands, write, tie his tie and shoelaces, and perform many other functions necessary in one's daily routine. However, Gillis (16) has very aptly emphasized that the type of upper extremity prosthesis must be chosen to meet the needs of the patient. For example, a hook which is very useful to a workman would have comparatively little value to a man whose vocation is politics.

Postoperative Care. Patients with amputations require more than the average postoperative care because of the *danger of infection and its seriousness when present.*

Postoperative care differs considerably, depending upon whether or not the wound was left open or closed. If an open amputation was performed, one of the most important features in postoperative care is application of traction on the skin of the stump and its maintenance until healing is well advanced. This is readily accomplished by gluing sterile circular stockinette to the skin of the remainder of the extremity, permitting several inches of stockinette to dangle below the end of the stump to which a rope for traction can be tied. Sufficient traction (5 to 10 pounds) is applied to bring the flaps down.

the deep muscles at a still higher level, thus permitting exposure of the bone so it can be transected at least several centimeters proximal to the skin incision. The periosteum is cleanly incised, but the bone is sawed across immediately distal to this level without removing a cuff of periosteum from the bone end; exposure of bone free from periosteum would encourage sequestration, since infection will develop in such a high percentage of cases for which this operation is chosen. The use of catgut is preferred to silk or cotton in an open amputation. No closing sutures are taken. Traction must be applied, by adhesive or other means, immediately after amputation to prevent retraction of the skin and soft tissues above the bone. The traction can be released to allow dressings as indicated. It must be maintained until the open wound has completely healed (12).

AMPUTATION THROUGH THE THIGH. When the amputation is performed in the middle third of the thigh or higher, an end-weight-bearing prosthesis cannot be used since most of the weight is borne by the ischium. The scar should be posterior and above the end of the bone. To achieve this location, a long anterior flap and a short posterior flap are cut. It is advisable to save as much stump as possible down to within a few inches of the knee. Therefore, the position of the scar can be ignored if more length can be obtained by some other incision. Up until recently, short amputations of the thigh could not be fitted with efficient artificial limbs, but, since the introduction of the hip control limb, fair action can be obtained with a 2- or 3-inch stump. The original type of artificial limb, which was held in place by shoulder straps, tends, with certain movements, to fall away from the stump when it is short. When a disarticulation at the *hip* is necessary, the modern pelvic socket type of prosthesis will be surprisingly satisfactory. All muscles except those of the buttock should be removed.

AMPUTATION NEAR THE KNEE. Amputations at this level are particularly adaptable to artificial limbs sustaining considerable weight, thereby lending stability to the prosthesis. The *Gritti–Stokes amputation* is performed at the knee joint; the lower end of the femur and posterior part of the patella are removed with the saw so that the patella can be rotated and approximated against the end of the femur. Since an end-weight-bearing stump is thus produced, the skin over the end of the bone should be the toughest available. Using a long anterior flap, the skin normally overlying the patella becomes the weight-bearing portion of the stump. The anterior half of the patella is anchored to the end of the femur, where it heals in place. This procedure has been modified by Callander (13), who makes long anterior and posterior flaps and saws across the lower end of the femur above the condyles just proximal to the abductor tubercle, removing the patella, so that the stump of the femur may fit into the tendinous patellar socket and thus allow weight-bearing. This amputation is becoming quite popular and can be fitted very satisfactorily with an artificial limb, utilizing considerable weight-bearing, the chief advantage of which is stabilization of the artificial limb.

AMPUTATION THROUGH THE LEG. As stated previously, optimum length of a leg stump is 5 to 7 inches. Weight is borne on the side of the head and under the tubercle of the tibia, against the conical shaped bucket of the prosthesis. For this reason, the patient can rarely stand all day on his feet because of skin irritation and pain at the site of the weight-bearing. The skin chafes and blisters, and hair follicle infections are common. However, the stump is easily fitted with a prosthesis, and the patient can learn to walk with very little limp. In women who do not need to be on their feet very long at a time, it is particularly adaptable because of the good cosmetic appearance. The fibula should be sectioned about an inch above the level of the tibia and the corners smoothed off well. Although many surgeons remove it entirely, its presence is helpful in rotating the prosthesis. Excision of the fibula is advisable, when possible, in short leg stumps because it yields a rounder and more conical stump. Amputations in the lower third of the leg are considered unsatisfactory by most surgeons because of poor circulation and increased sensitivity and by prosthesis makers because the long stump may actually interfere with the ankle mechanism. If not enough leg stump remains to preserve the optimum 6 inches of tibia, it

ful phantom) is comparatively rare. For example, in a series of 2,284 amputees seen in American army hospitals during World War II, Ewalt and associates (19) noted that only 8 complained of a painful phantom. The phantom limb has been described as an hallucination (20). As time passes, the phantom usually disappears into the stump. The painful phantom is often difficult to treat; operation such as removal of an amputation neuroma seldom, if ever, helps. Other therapy should be tried. Rarely is resection of the sensory cortex (lobotomy) justified.

Rehabilitation. Obviously, all effort must be made to fit the stump with a prosthesis, although it is recognized that certain prerequisites must be met before this can be done. The important prerequisites may be enumerated as follows: 1. adequate shrinkage of the stump; 2. flexible skin over the stump without adherent scar; and 3. well-developed muscles to control the stump.

It is essential that the fitting of the limb should not be postponed, lest sufficient muscle and bone atrophy take place to seriously delay walking. Such delay in starting function with the artificial limb is particularly serious in the aged and may even be the primary factor in inability of the patient to learn how to use a prosthesis. Graded muscular exercise is important, particularly in lower limb amputees; for bilateral knee amputees, proper balance is impossible without strong abdominal muscles.

SHRINKAGE OF THE STUMP. This is one of the most important prerequisites necessary to fitting a prosthesis. Shrinkage takes place for six to nine months after operation. It can rarely be accomplished to such a degree of rapidity as to allow fitting of the prosthesis sooner than two months after operation. One of the most effective mechanisms of obtaining shrinkage is to apply elastic bandages to the stump (Fig. 7); this can be started as soon as the sutures are removed and healing has taken place. Another very effective method of obtaining shrinkage is utilization of weight bearing in a temporary prosthesis, which can be constructed as a mold of the stump made with plaster bandages. After the mold has hardened, a peg of adequate length is attached and fixed with more plaster (Fig. 8); it is held in position by proper straps over the shoulder and around the waist.

PREVENTION OF CONTRACTURES. Contractures usually develop in the preoperative period of the patient's illness and should be avoided if at all possible, since they may be very difficult to eliminate once they develop to a severe degree. In general, contractures must be corrected before the prosthesis can be fitted.

SELECTION OF PROSTHESIS. The surgeon must be very familiar with the mechanisms and types of prostheses, but the fitting itself is a specialty of its own and is better left to the personnel dispensing the limbs. However, the surgeon must tell the leg fitter what type of prosthesis is best suited for the individual patient; moreover, he must know whether or

As stated previously, the traction need not interfere with dressings. It will require at least six or eight weeks for healing to progress far enough to allow any secondary operation which will be necessary after most guillotine operations. If a small granulating area remains at the end of the stump, it can be excised and the skin flaps undermined sufficiently to allow closure without tension. If the bone end is long, the end may be freed and a small portion sawed off to allow closure. However, when bone is removed in the presence of an ulcer, there must be absolutely no evidence of infection remaining in the wound. After this reamputation operation as well as after the primary one, appropriate antibiotic therapy should be given for a few days to minimize possibility of infection. The treatment of the stump from the prosthetic standpoint is discussed later.

If the *stump has been closed*, the wound should not be dressed every day, but the temperature and pulse chart must be observed closely for an elevation which might be indicative of development of infection. Likewise, if the patient complains of pain in the stump, the dressings should be changed and the stump inspected. If there is sufficient redness, edema, and tenderness to indicate the presence of infection, a number of sutures must be removed to allow drainage. Frequently, it will be advisable to open the wound completely. In the presence of infection, the wound should be dressed and irrigated daily. Carrel Dakin treatment or application of zinc peroxide may be utilized. Wound secretions should be cultured as soon as infection is suspected so that specific immediate therapy may be instituted. When such a wound has been opened the skin flaps tend to retract. After the infection has subsided, it is, therefore, usually necessary to exert some type of traction on the skin to bring it down into its former position so that the stump will be covered adequately with soft tissue. It should be emphasized, however, that traction should not be applied to any stump when an acute infection is present. The stump should be placed in a comfortable position. Arms should be placed in moderate abduction. For the thigh and knee a slight amount of flexion is permissible, but elevation on pillows is to be condemned. To prevent muscle atrophy the stump must be fitted early for a prosthesis (9). Perhaps a still more important reason for making early plans for fitting a prosthesis is the effect on morale. In fact, the early fitting of a prosthesis is so important that a temporary appliance of fiber or equivalent material may be indicated (Thompson, 17). As soon as shrinking of the stump has been achieved, a permanent limb is fitted.

Complications. *Reamputation* is occasionally indicated when not originally planned. For example, osteomyelitis of the end of the bone, or tender bone spurs in the absence of infection may necessitate reamputation. Not infrequently, tender scars are so troublesome that a prosthesis cannot be worn comfortably. In such an instance, simple excision of the scar with interposition of some soft tissue, preferably subcutaneous fat and fascia (if the scar was adherent to the bone or directly overlying it) will be indicated but is not always successful. Local tenderness associated with a *neuroma* may justify excision of the end of the nerve, but not reamputation. White (18) has emphasized that repeated excisions of neuromas are contraindicated; if relief is not obtained by one excision, another excision at a later date will rarely be successful. Sympathectomy may be tried if local measures fail. Local pain, burning, and tenderness in the stump may be treated by sympathetic block or sympathectomy; on rare occasions, section of the rhinothalamic tract may be indicated. Occasionally an ulcer develops at the end of the stump and stubbornly refuses to heal, frequently because the bone is too long. Excision of a few centimeters of bone together with scar tissue or reamputation at a higher level will be indicated depending upon the circulation in the stump. If the bone has adequate coverage with soft tissue, simple excision of the ulcer and scar tissue may suffice. In any case, these secondary procedures *must not be performed until all evidence of infection*—such as induration, redness, edema—*has disappeared.*

Phantom limb refers to the complaint of many amputees of normal sensations in the absent extremity. A sensation of pain (pain-

not it fits and meets the requirements of the stump.

Perhaps the best wood for prostheses is willow, and the best metal is duraluminum (alloy of aluminum) because it is light. A fiber made from rag pulp is often used because it is so readily adjustable. For upper extremity prostheses, laminated plastic is best suited for the socket. Leather is being used less and less, largely because it lacks stability and absorbs odors. The socket is the element requiring the greatest skill in construction. It is the portion of the prosthesis into which the stump fits and through which the stump motivates the prosthesis.

Cineplastic Amputations. This term may be defined as being any type of plastic operation on an amputation stump (usually on the upper extremity) which allows transmission of voluntary movement to the artificial limb. The procedure was first utilized by Vanghetti, an Italian, in 1898. At the present time the method is relatively unsatisfactory, but efforts toward development of such improvements should be encouraged. A tube flap of skin is made over the muscle to be utilized and threaded through an opening made in the body of the muscle whose function is to be utilized. The defect made by raising the tube skin flap is closed with or without a skin graft as indicated. After healing has taken place, a peg is placed through the opening and the ends of the peg attached to levers on the prosthesis so that, when the muscle contracts, the hand, for example, will open or close. Although delicate movements of fingers cannot be duplicated, the function of grasping and releasing objects with the mechanical hand should be possible if sufficient arm stump is available and the operation is successful. The points of attachment on the extremity are called "motors." To be effective, they should have at least a 2 or 3 cm. range in motion induced by contraction of the muscle. The pioneer work in cineplastic amputations has been done by Kessler (21). Details of progress made in the various aspects of amputation may be found in the publications by the National Research Council (22). These amputations have a very limited application but are, however, proving to be of some value in bilateral upper arm amputees, where cinematization of the biceps and/or the pectoral muscles supply valuable motors to motivate the prosthesis.

may proceed to the point of perforation with comparatively few symptoms. For that reason, when acute abdominal manifestations suggestive of appendicitis develop in a diabetic patient, delay in operation is hazardous, particularly because such acute lesions as appendicitis and acute cholecystitis are less apt to subside and are more prone to progress to perforation than in nondiabetic patients.

On the other hand, it is not generally appreciated that patients in diabetic acidosis or impending coma may develop acute abdominal symptoms not unlike those of acute appendicitis, acute pancreatitis, and so forth, including nausea, vomiting, abdominal pain, rigidity, and leukocytosis. What a serious error it would be to submit such a diabetic patient with impending coma to operation! Usually, however, the differentiation can be made by the sequence of development of vomiting and pain. In diabetic acidosis, the vomiting is apt to precede the pain, whereas in appendicitis the pain precedes the vomiting. Routine examination of the urine for sugar reveals the existence of diabetes which, of course, should lead to the true explanation of the clinical picture.

Trauma in diabetics likewise must be treated with unusual care because any significant injury acts like an operative procedure by aggravating the diabetic state. In *fractures*, particularly, the insulin requirements will have to be raised considerably. For example, a diabetic remaining sugar-free on 20 to 30 units daily may require 70 to 100 units daily for many days or weeks following a severe fracture, such as one involving the hip or shaft of the femur.

Infections in diabetes call for an increase in the insulin requirements. Failure to appreciate this fact may result in acidosis or even coma. The explanation of this phenomenon is not clear, but the theory most commonly accepted is that, on such occasions, there is a decrease of endogenous insulin secreted by the pancreas. Greene and Keohen (2) found no evidence that the amount of fever played any role in the insulin needs.

Many other surgical diseases, including hyperthyroidism and cholecystitis, increase the intensity of diabetes. Naturally, the presence of the two diseases will complicate the therapy and require more skillful care.

The belief is sometimes expressed that elimination of such a disease as cholecystitis will decrease the amount of insulin needed. However, in an extensive study of 76 diabetic patients having had cholecystectomy at the New England Deaconess Hospital, Eisele (3) did not note any significant decrease in insulin requirements after operation. Control of cholecystic symptoms was satisfactory although complications as found at operation were much more common (22 per cent of the series had hydrops, empyema, gangrene, perforation, or pancreatitis), indicating that the need for surgical care of bladder disease is just as strongly indicated in diabetics as in nondiabetics.

The mortality rate for cholecystectomy will be no higher in diabetics than in nondiabetics, providing meticulous care is taken to control the diabetes and to treat complications skillfully.

Preoperative Preparation. The operative mortality in diabetics has dropped tremendously since the introduction of insulin, as shown in a survey of the literature by John (4) who noted that in 2,023 operations on diabetic patients before the advent of insulin the mortality was 24.2 per cent; whereas, in 14,251 operations performed with preoperative insulin therapy (but before the advent of chemotherapy), the mortality was only 5 per cent. Other factors are, of course, important in reaching a low mortality. For example, it is particularly important that the glycogen reserve of the liver be maintained. Satisfactory glycogen reserve can be attained only by the administration of a diet containing adequate amounts of carbohydrate, protein, vitamins, fluids, and so forth, along with proper insulin therapy.

Arteriosclerosis is frequent in diabetics. These patients should therefore be submitted to thorough examination, paying particular attention to the heart and kidneys, organs which are apt to be seriously affected by arteriosclerosis of the advanced type. Generally speaking, because of the features just mentioned, the best results in diabetic surgery will be attainable only by the utmost of co-operation between the internist and the surgeon. Lack of such joint effort perhaps accounts in part for the large variation in the mortality following operation (4 to 30 per

19

SURGERY IN DIABETES

Surgical Diseases Unrelated to Diabetes
Surgical Diseases Secondary to Diabetes

Diabetes is a chronic metabolic disease, *largely hereditary, resulting from an insufficient* production or a diminished effectiveness of insulin, which is an internal secretion produced by *the islands of Langerhans in the* pancreas. The discovery of insulin has lengthened life considerably for diabetics, thus increasing their need for surgical therapy. Even if the insulinase inhibitors, recently introduced in the treatment of certain types of diabetes, supplant insulin, they will probably not affect the surgical aspects of the disease.

There are a number of surgical lesions (particularly infections) which increase the severity of diabetes. This fact must be appreciated, and the dosage of insulin increased lest diabetic coma develop as a result of the infection. Conversely, *it is true that diabetic* patients are prone to develop infection or gangrene of the toes and feet; McLaughlin and Wiedman (1) noted that one or the other of these lesions was present in 6.7 per cent of 802 *diabetics admitted to their hospital.*

Diabetics, particularly adults, appear much older in many ways than their true age. This is explained, in part, by the fact that they are much more prone to develop arteriosclerosis. Joslin has stated that a diabetic patient is as old as his real age plus the number of years he has had diabetes. The arteriosclerosis which develops is generalized in character, affecting the coronary and renal vessels, as well as those of the extremities.

Wounds in diabetic patients, in the absence of complicating factors, heal as readily as wounds in nondiabetics *but because diabetics* have a lowered resistance to bacteria, infection is more likely. It has been shown that the blood serum of diabetics has a lower opsonic index toward tubercle bacilli, staphylococci, and streptococci than the serum of normal people.

This discussion of surgical conditions in diabetes will be divided into a consideration of lesions unrelated to diabetes and lesions secondary to diabetes. The latter group is much more serious than the former, requires a different type of therapy, and is associated with a much higher mortality.

SURGICAL DISEASES UNRELATED TO DIABETES

Numerous surgical lesions requiring operation develop in the presence of diabetes but are entirely unrelated thereto. Operations under such circumstances may be carried out with comparative safety, so long as the diabetes *is under control. This requires* special care because any anesthesia and operation temporarily aggravate the diabetic state. With this precaution met, most surgeons have such fortunate results in this group of patients *that they do not consider* diabetes as a contraindication for either emergency or elective operation.

However, it must still be remembered and emphasized that even a controlled diabetic patient is distinctly not as safe a risk as a nondiabetic patient, e.g., the incidence of pneumonia in abdominal operations in the presence of diabetes is greater *than in* nondiabetic patients. The mortality following operations for carcinoma is considerably higher when there is a coincident diabetes.

Clinical manifestations in many acute sur*gical conditions, particularly* those within the abdomen, are milder when they develop in diabetes, e.g., an acutely inflamed appendix

may proceed to the point of perforation with comparatively few symptoms. For that reason, when acute abdominal manifestations suggestive of appendicitis develop in a diabetic patient, delay in operation is hazardous, particularly because such acute lesions as appendicitis and acute cholecystitis are less apt to subside and are more prone to progress to perforation than in nondiabetic patients.

On the other hand, it is not generally appreciated that patients in diabetic acidosis or impending coma may develop acute abdominal symptoms not unlike those of acute appendicitis, acute pancreatitis, and so forth, including nausea, vomiting, abdominal pain, rigidity, and leukocytosis. What a serious error it would be to submit such a diabetic patient with impending coma to operation! Usually, however, the differentiation can be made by the sequence of development of vomiting and pain. In diabetic acidosis, the vomiting is apt to precede the pain, whereas in appendicitis the pain precedes the vomiting. Routine examination of the urine for sugar reveals the existence of diabetes which, of course, should lead to the true explanation of the clinical picture.

Trauma in diabetics likewise must be treated with unusual care because any significant injury acts like an operative procedure by aggravating the diabetic state. In *fractures*, particularly, the insulin requirements will have to be raised considerably. For example, a diabetic remaining sugar-free on 20 to 30 units daily may require 70 to 100 *units daily* for many days or weeks following a severe fracture, such as one involving the hip or shaft of the femur.

Infections in diabetes call for an increase in the insulin requirements. Failure to appreciate this fact may result in acidosis or even coma. The explanation of this phenomenon is not clear, but the theory most commonly accepted is that, on such occasions, there is a decrease of endogenous insulin secreted by the pancreas. Greene and Keohen (2) found no evidence that the amount of fever played any role in the insulin needs.

Many other surgical diseases, including hyperthyroidism and cholecystitis, increase the intensity of diabetes. Naturally, the presence of the two diseases will complicate the therapy and require more skillful care.

The belief is sometimes expressed that elimination of such a disease as cholecystitis will decrease the amount of insulin needed. However, in an extensive study of 76 diabetic patients having had cholecystectomy at the New England Deaconess Hospital, Eisele (3) did not note any significant decrease in insulin requirements after operation. Control of cholecystic symptoms was satisfactory although complications as found at operation were much more common (22 per cent of the series had hydrops, empyema, gangrene, perforation, or pancreatitis), indicating that the need for surgical care of bladder disease is just as strongly indicated in diabetics as in nondiabetics.

The mortality rate for cholecystectomy will be no higher in diabetics than in nondiabetics, providing meticulous care is taken to control the diabetes and to treat complications skillfully.

Preoperative Preparation. The operative mortality in diabetics has dropped tremendously since the introduction of insulin, as shown in a survey of the literature by John (4) who noted that in 2,023 operations on diabetic patients before the advent of insulin the mortality was 24.2 per cent; whereas, in 14,251 operations performed with preoperative insulin therapy (but before the advent of chemotherapy), the mortality was only 5 per cent. Other factors are, of course, important in reaching a low mortality. For example, it is particularly important that the glycogen reserve of the liver be maintained. Satisfactory glycogen reserve can be attained only by the administration of a diet containing adequate amounts of carbohydrate, protein, vitamins, fluids, and so forth, along with proper insulin therapy.

Arteriosclerosis is frequent in diabetics. These patients should therefore be submitted to thorough examination, paying particular attention to the heart and kidneys, organs which are apt to be seriously affected by arteriosclerosis of the advanced type. Generally speaking, because of the features just mentioned, the best results in diabetic surgery will be attainable only by the utmost of co-operation between the internist and the surgeon. Lack of such joint effort perhaps accounts in part for the large variation in the mortality following operation (4 to 30 per

cent) in diabetic patients in the various clinics throughout the country.

Elective operations should be preceded by a preliminary period of preparation and study so that the insulin requirements may be fully understood. Though protamine insulin has been of considerable value in the treatment of the surgical diabetic patient, its prolonged action may serve as a disadvantage, making it necessary sometimes to resort to feedings at bedtime and between meals. In general, it is more difficult to use protamine insulin in children. The amount of carbohydrate, protein, and fat in the diet will naturally depend on the severity of the diabetes and will vary from 175 to 250 gm., 75 to 80 gm., and 70 to 90 gm., respectively. If malnutrition is present, administration of a high protein diet (1.5 to 2.0 gm. per kilogram) should be given preoperatively until operability is satisfactory.

Nutritional preoperative preparation varies somewhat, depending on the severity of the diabetes. Breakfast and its insulin is omitted; the usual dose of insulin (preferably depot insulin) and 60 gm. of glucose by mouth may be given two or three hours before operation. Intravenous glucose (1,000 ml. of 5 per cent) may be substituted for the oral glucose. Protamine insulin is very satisfactory as the preoperative dose because of the excellent protection during the operation, but should not be given if it has not been used in the routine care of the patient previously. Hypodermoclysis or intravenous fluids are not given before operation unless there are specific indications. The dose of drugs, preoperative and otherwise, should be decreased to slightly under the average dose because diabetic patients are somewhat less tolerant to drugs than are nondiabetic patients.

In *emergency* operations there will obviously not be sufficient time to make the urine sugar-free. The administration of such massive doses as to attain this effect in a few hours would be unsafe because of the danger of severe hypoglycemia. However, if possible, the urine should be free from diacetic acid.

Anesthesia in Diabetes. No single anesthetic agent can be used effectively and safely as a routine in diabetic patients. Certain of the gases, including nitrous oxide, ethylene, and cyclopropane are relatively innocuous. One of the greatest anesthetic dangers in diabetic patients lies in the production of acidosis. Unlike the three agents mentioned above, prolonged administration of ether has a distinct tendency to produce acidosis. Furthermore, ether results in hyperglycemia, either through defective utilization of carbohydrates, by prevention of conversion of dextrose to glycogen, or by depletion of hepatic glycogen. Asphyxiation of tissues may be partly responsible for these changes. At any rate, anoxia should be meticulously avoided, regardless of the agent used. Chloroform should never be used on account of the severe damage inflicted by it upon the liver. Avertin should not be used because of its deleterious effect on the liver which, however, is obviously not as pronounced as that produced by chloroform.

Local anesthesia is, in general, the safest and should be used whenever feasible. For amputations, spinal anesthesia (50 to 75 mg. procaine) will probably be as free from deleterious effects as any other type. However, in doses large enough to permit abdominal operations, spinal anesthesia is probably no less hazardous than a general anesthetic. For abdominal operations gas-ether anesthesia (utilizing nitrous oxide or perhaps ethylene) will be as safe as any other. Intravenous anesthesia (e.g., sodium pentothal) may be used when relaxation need not be complete or prolonged, but must be given with considerable caution.

Postoperative Care. The maintenance of proper fluid intake is an especially important obligation in the care of diabetic patients following operation. If the operation is a major celiotomy and oral intake is limited or absent during the first 24 to 48 hours, the intravenous route will be indicated. Since there is normally a mild retention of sodium chloride and water for 24 to 48 hours after operation, it is important to avoid excessive infusion of fluids (not more than 30 ml. per kilogram and a total of 4 gm. of sodium chloride) during the first 24 hours unless an electrolyte deficiency existed at the time of operation. In this case, it should be corrected before the anesthetic is started. Intravenous glucose will have to be covered by insulin, administered in amounts equivalent to that needed preoperatively for a given amount of carbohydrate. In

general, intake and output should be equal and adequate.

To prevent the possible development of insulin shock, relatively small doses of insulin at frequent intervals are preferable. The interval between doses for a day or two following operation should be shorter than preoperatively because the duration of its effect is shortened. It is preferable to administer too little insulin rather than too much. Blood sugar determinations are supposedly more accurate than urine analyses in determining the amount of insulin to administer, but each test should be made at intervals of four to eight hours during the first day or two. It should be remembered that slight glycosuria does little harm whereas insulin coma (hypoglycemia) may give rise to serious or even fatal consequences, even though recognized early and treated. For this reason, little or no attempt is made to make the urine sugar-free during the first three or four days postoperatively. However, the urine must be watched for acetone, and insulin with ample fluids must be given as indicated.

All nurses and physicians attending the diabetic patient should be trained to detect the manifestations of insulin shock. Such symptoms as weakness, sweating, pallor, hunger, and mental confusion demand consideration of such a diagnosis. The problem can be settled by a blood sugar determination. However, the condition is so serious that it should be recognized and proper therapy (intravenous glucose) instituted without waiting for the blood sugar report.

The usual postoperative instructions, such as breathing exercises, frequent changes of position, and ambulation, are ordered. If the operation has been of a type resulting in bacterial contamination (e.g., colectomy), prophylactic chemotherapy—such as 600,000 units of penicillin and 2 grams of streptomycin per day—is given, particularly since diabetic patients tolerate infection poorly. If appetite is regained slowly, the dietitian should be consulted, and acceptable foods desired by the patient made available. More details of preoperative and postoperative care in diabetics may be found in a publication by Shuman (5).

McKittrick and Root (6) suggest a very simple and practical method of determining the amount of insulin required during the first few postoperative days, namely: "(1) Test the urine (Benedict's test) every four hours and (2) give insulin (crystalline), 15 units if the reaction is red, 10 units if it is yellow, and 5 units if it is yellowgreen." Such procedure is obviously only an approximate method of determining the amount of insulin needed but, since a definite mathematical method is unavailable, this simple rule will be found useful.

Oral feedings, including fruit juice and ginger ale, are administered as soon as tolerated, followed, on the second or third day, by portions of solid food more readily tolerated. Attempt should be made, particularly after the first 24 hours, to reach a daily carbohydrate intake of 100 to 150 gm. If the oral intake falls short of this amount, the remainder may be given as 5 per cent glucose intravenously or as 2.5 per cent glucose in physiologic sodium chloride solution subcutaneously.

SURGICAL DISEASES SECONDARY TO DIABETES

Incidence. Among the complications of diabetes or surgical diseases secondary to it, atherosclerosis is perhaps the most significant; it occurs particularly in the coronary arteries, renal arteries, and aorta. Atherosclerosis refers particularly to the degenerative aspects of arteriosclerosis. These arterial changes are much more common in diabetics than in nondiabetics. For example, in 1,214 diabetic autopsies Bell (7) noted that coronary atherosclerosis caused three times as many deaths (in females) in diabetics as in nondiabetics; this lesion was twice as common in males as it was in females. In his series, gangrene was 40 times as frequent in diabetic as in nondiabetic females past 50 years of age. Bell also noted that in those persons past 40 years of age atherosclerosis was the cause of death in 54 per cent of diabetics compared to 29 per cent in nondiabetics. Other important, complicating diseases more commonly observed in diabetics than nondiabetics are cataracts, retinopathies, prostatic hypertrophy, and other neuropathies discussed in detail by Goodman (8). The increased incidence of infection is perhaps of more importance than that of any of the conditions men-

Fig. 1. Deep plantar abscess in foot of a diabetic. Large patches of gangrene are also present. In this case amputation was necessary. Without the development of gangrene this abscess would have been treated by incision as in a nondiabetic.

tioned above; the various aspects are discussed in detail below.

Infections. As stated previously, infection is a common complication of diabetes. Although it may develop anywhere in the body, it is much more common in the lower extremities. Discussion of infection in this chapter will, therefore, be limited to those in the foot and leg. Years ago, before the advent of chemotherapy, infection associated with gangrene in the extremities of diabetics was very serious and often made emergency amputation necessary (9). Now infection, even in the presence of gangrene, is treated conservatively with simple surgery and antibiotics. After subsidence of the infection, gangrene is treated as discussed later in this chapter.

A serious infection may frequently develop in the foot and leg of a diabetic patient with (Fig. 1) or without gangrene. So many features are different from those in gangrene that the two conditions should be discussed separately. In the first place, infection is not dependent upon arterial deficiency and may start spontaneously or follow slight trauma. Such local manifestations as redness and swelling are present; but pain and tenderness are apt to be minimal. Spread may occur rapidly from the toe into the adjacent soft tissues, plantar spaces, and often involves underlying bone, partly because of the relative absence of pain. There is, indeed, a real hypoesthesia due, no doubt, to diabetic neuropathy. Sensation may be completely absent, and incisions can often be made painlessly without anesthesia. The amount of fever is extremely variable as is also leukocytosis. The increase in severity of diabetes by infection has already been discussed; this feature and the tendency toward rapid spread of the infection constitute reasons why the infection should receive prompt attention and treatment. Yet the prognosis in the face of neurologic changes without arterial impairment is unusually good.

Treatment. The need for prophylactic measures in the treatment of infections of the feet cannot be emphasized too strongly. Since gangrene or infection is so apt to follow trivial injuries in diabetes, it is essential that diabetic patients avoid trauma to their feet. Epidermophytosis should be watched for at all times and treated in its incipiency. Hot-water bottles, cold weather, new shoes, wrinkles in hosiery, electric pads, and the like, may cause trivial injuries which may serve as the instigator of serious trouble. The care of nails, corns, and so forth, should be entrusted to someone (not necessarily the patient) who is careful and experienced. Amputation need be considered only rarely, but incision with adequate drainage is urgently indicated when pus is present. The differentiation between a cellulitis and an abscess is frequently very difficult because of the absence of the usual inflammatory signs. Moreover, the infection burrows so rapidly and readily along fascial planes and tendons that any pus present will

not be under enough tension to produce fluctuation.

In general, an infection in a diabetic is treated the same as in a nondiabetic and often heals remarkably well. It is, nevertheless, more important that incision not be delayed when pus is present. Moreover, the incision for drainage must be adequate and must extend upward as far as the infection has burrowed. Rubber drains are used as indicated; but, in general, incisions should be sufficiently generous not to require drains to maintain drainage. Osteomyelitis of the tarsal bones also occurs and, like soft tissue infection, heals well with adequate drainage and chemotherapy, particularly in the presence of neuropathy.

When infections develop in the hand they are likewise serious because of the rapidity with which they spread along the sheaths, fascial spaces, and even subcutaneous tissue.

Chemotherapy should be instituted immediately, given in large doses, and maintained for several days after the signs of infection disappear. Penicillin in doses of 500,000 to 800,000 units and streptomycin in doses of 2 or 3 gm. per day may be tried initially. In view of the added danger of gangrene in diabetes, a culture should be taken as soon as possible, and sensitivity of the organism to the various antibiotics determined. After this data is obtained, the antibiotic shown to be most effective in vitro should be used, unless the infection has already subsided under the initial therapy.

Carbuncle. It is important to emphasize that carbuncles are much more serious in diabetic patients than in nondiabetics and, therefore, require more care in therapy. They are usually located on the back of the neck and commonly occur when the diabetes is out of control. They are so definitely related to diabetes that all patients with carbuncles should at once have a urine examination. Carbuncles, like other infections, increase the severity of diabetes, making it necessary to watch the urine and blood sugar daily. It will be necessary to increase the amount of insulin while the infection increases in intensity and decrease it as drainage is established. To prevent development of carbuncles, diabetic patients should not shave their necks and should, under no circumstance, squeeze or irritate hair follicle infections.

Carbuncles in diabetic patients may be treated with or without surgical drainage; the decision is now greatly influenced by the effect of chemotherapy. It is frequently difficult to determine when drainage should be established. Ordinarily, if the carbuncle is producing no fever or pain, and still remains relatively small in size, treatment may consist of radiotherapy and intensive chemotherapy. Local tenderness, fever, and especially fluctuation are usually indications for incision to establish drainage. The patient should be confined to bed and instructed to eliminate activity which would result in movement of the neck. Since the offending organism is a staphylococcus, penicillin is ordinarily effective but frequently is not, due to the increasing resistance of this organism.

Gangrene. Diabetic gangrene is serious because of its frequency and poor prognosis unless treatment is carried out very accurately. In a large series of cases collected from the literature, John (4) noticed an incidence of 5 per cent, and McLaughlin and Wiedman (1) of 6.7 per cent, in diabetic patients. The development of gangrene is determined by the degree of vascular occlusion (arteriosclerosis) and bears little relationship to the severity of the diabetes. The gangrene may be "dry," i.e., of the type usually seen in arteriosclerosis, but is more apt to be "wet" because of the high incidence of infection.

Diabetic gangrene may occur anywhere on the body but is usually located on the toes or feet, where it starts as a small gangrenous area (Fig. 2). Occasionally, the process is superimposed upon an infectious process because of the interference to circulation by the edema, and so forth, incident to the infection (Fig. 3). Rosenberg and London (10) have very appropriately emphasized that "in a limb presenting a gangrenous lesion, the prognosis may be paradoxically better for the diabetic than for the nondiabetic."

Pain at the site of the gangrene or of the intermittent claudication type in the leg is apt to be minor in character. Examination of the extremity proximal to the gangrene will reveal a variable degree of impairment of blood supply; the skin is apt to be dry, thin, and parchmentlike, and the nails dry and

Fig. 2. Gangrene of the fourth toe in a diabetic. In this case, without involvement of the foot, transmetatarsal amputation just proximal to the metatarsal heads is indicated.

brittle. Other manifestations of damage to the blood supply may include pallor of the foot upon elevation and a slowly developing rubor or cyanosis upon dependency. The dorsalis pedis, posterior tibial, and frequently the popliteal pulses on the affected side are apt to be absent. If infection is present, there will be edema, redness, and so forth, as described later in this chapter.

TREATMENT. Preventive measures are of the greatest importance in diabetic gangrene, as has been discussed under Infections. In definitive therapy, rest in bed is, of course, imperative; the leg should be put in a position where blanching of the foot is minimal and precautions taken lest decubital ulcers develop. If the gangrenous area is dry and not infected, dry sterile dressings should be applied to prevent contamination and subsequent infection. If infection is present, wet dressings consisting of physiologic saline, 50 per cent alcohol, or some weak antiseptic should be applied. In either case, the foot should be protected with a cradle. Should the infection become fulminating, increased chemotherapeutic coverage may be necessary, and refrigeration in preparation for amputation may be indicated.

The major definitive pattern of treatment of diabetic gangrene has changed considerably during the past several years and the mortality reduced greatly. Amputation has become much less radical. The predominant type has changed from leg or thigh to local (i.e., toe or part of the foot). For example, Regan and associates (11) noted that in their experience between 1933 and 1939 the percentage of thigh amputations was 71 per cent and toe amputations 29 per cent. In the period between 1945 and 1948 the frequency of these types of amputation was reversed—thigh and leg being 30 per cent and toe amputations 70 per cent. In their last series of patients, a large proportion of the major amputations were in patients who had an unsuccessful local (toe) amputation. Moreover, it has become more and more apparent that the clinical impression as to the state of the circulation is by no means a correct indication as to how successful a local amputation might be. Years ago, before the advent of chemotherapy, local amputation instead of a high amputation was a serious error and often resulted in the death of the patient. In recent years, largely because of chemotherapy, local amputation seldom results in death of the patient even though the stump develops gangrene or fails to heal. Regan and associates have reported a mortality rate of 4.1 per cent following amputations in diabetics in a period between 1945 and 1948 and a rate of 8.8 for the period between 1940 and 1945, indicating that improvement in mortality figures continues. They likewise reported that in the three periods, 1933 to 1939, 1940 to 1944, and 1945 to 1948, successful local amputations (toe or part of the foot) had changed to 46 per cent, 63 per cent, and 86 per cent respectively. In local amputations of the toe only, closure of the stump will usually be impossible or unjustified. After granulations form, skin grafts are applied.

McKittrick and associates (12) favor transmetatarsal amputation over amputation of one or two toes, partly because removal of a toe, especially the great toe, alters the "weight bearing and increases the vulnerability of the remaining toes." The operation is indicated primarily in the presence of gan-

Fig. 3. Extensive diabetic gangrene of the foot. The patient was a 45-year-old female. A moderate amount of infection was present, as is commonly noted in diabetic gangrene, thereby making amputation more urgent than in gangrene due to arteriosclerosis alone. Note the cyanosis below and distal to the necrotic area with impending gangrene of the toes.

grene of one or more toes without gangrene of the dorsal or plantar aspect of the foot. Obviously, there must not be any acute infection.

Wheelock, McKittrick, and Root (13) have indicated that there are two groups of diabetic patients for whom transmetatarsal amputation may be indicated. The smaller group consists of patients who have very good blood supply but who have neuropathy or severe infection. The operation may be performed to eliminate a chronic or recurring ulcer on the palmar surface of the forefoot (Fig. 4A) or to reconstruct a foot after an acute infection has destroyed part of it, and all infection has been eliminated. The second, larger group consists of patients with arterial insufficiency. Usually the pedal pulses are absent. Areas of skin necrosis may be present on one or more toes. Ulcers on the base of the great toe (Fig. 4B) are best treated by transmetatarsal amputation. There must be no necrosis on the dorsum, proximal to the metatarsal phalangeal joint. In general, the operation cannot be done unless the local condition is stabilized. This is achieved by bed rest, antibiotics, and surgical drainage if necessary. The above authors emphasize that three weeks may be required to obtain this stabilization; rarely, more time is required to obtain it and to arrive at a decision concerning the type of operative procedure to perform. Details of operative technic and postoperative care are described by these authors. Of 433 transmetatarsal amputations performed by them, 67 were classified as in the neuropathic-infection group and 366 in the arterial-insufficiency group. The mortality rate in the entire group was 1.1 per cent; initially successful results were recorded in 83 per cent, and immediate failures in 15.7 per cent.

Smithwich (14) reports that if the temperature of the skin at the site of amputation is 75° F. or more after exposure of the extremity to a room temperature of 68° for one hour or if, after blanching of the foot by elevation,

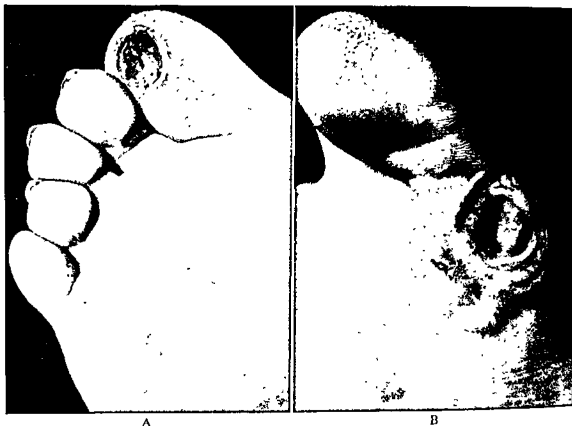

Fig. 4. Types of ulcers encountered in diabetes. In A there is an ulcer on the palmar surface of the great toe but there is also a patch of gangrenous skin on the dorsal surface; this foot is best treated by a transmetatarsal amputation. In B there is a penetrating ulcer at the base of the great toe without any gangrene. Transmetatarsal amputation is also indicated here but the edge of the ulcer encroaches closely on the expected suture line between the skin of the dorsal and ventral surfaces.

flushing in the dependent position begins in 20 seconds or less, collateral circulation is adequate for local amputations.

Sympathectomy is very helpful in diabetic gangrene, and in patients with minimal gangrene or ulceration it will promote healing in many patients without necessity of amputation.

Local amputation is much preferable to a high amputation (e.g., supracondylar) because the mortality rate is much lower and function is greatly superior. In fact, scarcely more than 50 per cent of diabetic patients having a supracondylar amputation will get back to work or wear prostheses successfully.

Miscellaneous Complications. *Furuncles.* Furuncles are also prevalent in diabetic patients and commonly become multiple (furunculosis). All patients with furunculosis should have their urine examined for sugar. Treatment is usually conservative, incising the larger ones as indicated (see also p. 91). Chemotherapy should be instituted, particularly if several furuncles are present. *Cholecystitis* cannot be classified as a true complication of diabetes, but it is true that the incidence of gallbladder disease is higher in diabetic than in nondiabetic patients. Some observers go so far as to state that in certain instances cholecystectomy will prevent the development of diabetes; obviously, proof of this is not at hand and would be difficult to obtain.

NEOPLASMS AND CYSTS: CLASSIFICATION AND SURGICAL PATHOLOGY

Malignant Neoplasms
Benign Neoplasms
Cysts

The term neoplasm is commonly referred to as "tumor" which, however, is not a synonym. The term *tumor* really refers to a swelling which, in general, may be classified into two general groups, inflammatory and neoplastic. This terminology, moreover, is not exact, because a neoplasm, such as keloid, may actually follow an injury. Certain cancers, too, follow chronic irritation; and there is some theoretical and experimental evidence that neoplasms are in reality expressions of repair, exaggerated or gone wrong. Nevertheless, the division into inflammatory and neoplastic tumors serves a useful purpose in diagnosis when one is confronted with a swelling of unknown etiology. Inflammatory tumors are discussed under their respective causes. A few congenital tumors that are not neoplastic—such as meningocele and spina bifida—are considered under cysts.

Neoplasms may be divided into two great groups, malignant and benign, but some have characteristics which are not consistent with either group. Both groups, moreover, have one feature in common, i.e., they are formed by the abnormal and purposeless multiplication of previously normal cells. When benign, the new growth resembles closely the tissue from which it originated; the cells are arranged in orderly fashion and, though the tumor may attain great size, it never jeopardizes the life of the host except that it may involve vital functions by pressure and occasionally by functional activity. Malignant neoplasms, on the other hand, consist of abnormal cells which tend, more or less, to approach the undifferentiated embryonic type; they are not orderly in growth, but invade and destroy adjacent tissues or spread to distant parts of the body and lead finally to the death of the individual. The reader is referred to the texts by Ackerman (1), Boyd (2), and others for detailed morphologic descriptions of the various types of neoplasms. The following classification, though in some cases imperfect or arbitrary, will be used in this text. In the next chapter, the general principles of *therapy* will be discussed.

Classification

A. Malignant Neoplasm. Etiology, clinical characteristics, microscopic features, types (carcinoma and sarcoma), and treatment
   I. Carcinoma (epithelial)
      1. Carcinoma of the skin and squamous mucous membranes: (*a*) Squamous cell carcinoma, (*b*) basal cell carcinoma, (*c*) malignant melanoma, (*d*) Paget's disease of the nipple
      2. *Carcinoma of glandular origin* (breast, urinary and genital tract, and other internal organs)
      3. *Miscellaneous carcinomas*
   II. Sarcoma (mesodermal)
      1. *Fibrosarcoma* (fibroblastic or spindle cell sarcoma)
      2. *Bone sarcoma* (classification, general features and types, i.e., osteogenic and nonosseous (or miscellaneous) sarcoma
      3. *Sarcoma of lymphoid tissue:* (*a*) simple lymphoma, (*b*) leukemia, (*c*) Hodgkin's disease, (*d*) lymphosarcoma
      4. *Miscellaneous sarcomas:* (*a*) liposarcoma, (*b*) rhabdomyosarcoma, (*c*) thymoma

III. Brain tumors
Neurocytoma

B. Benign Neoplasms. Etiology, clinical characteristics and types (based on cell of origin)
- I. Connective tissue origin
  1. *Fibrous tissue tumors:* (*a*) keloid, (*b*) simple fibroma, (*c*) epulis, (*d*) giant cell tumor
  2. *Fatty tissue tumors:* (*a*) lipoma, (*b*) xanthoma
  3. *Bone and cartilage tumors:* (*a*) osteochondroma, (*b*) chondroma, (*c*) bone cyst, (*d*) benign giant cell tumor, (*e*) multiple cystic disease
- II. Nervous tissue origin
- III. Blood vessel origin
  1. *Capillary hemangioma*
  2. *Hypertrophic hemangioma*
  3. *Cavernous hemangioma*
- IV. Lymphatic origin
  1. *Lymphangioma*
  2. *Thymoma*
- V. Muscle tissue origin (myoma, leiomyoma)
- VI. Mixed tissue origin
  1. *Mixed tumor*
  2. *Teratoma*
- VII. Epithelial cell origin
  1. *Adenoma*
  2. *Epithelial benign tumors of the skin:* (*a*) wart, (*b*) cutaneous horn, (*c*) mole (benign melanoma)
  3. *Jaw tumors:* (*a*) adamantinoma, (*b*) dentigerous cyst, (*c*) odontoma, (*d*) osseus tumors (fibrous osteoma)

C. Cysts
- I. Retention cysts (galactocele, mucocele, ranula, wen)
- II. Degeneration cysts
- III. Neoplastic cysts (ovarian, bone)
- IV. Dermoid cysts
- V. Congenital cysts (branchial cleft, thyroglossal duct, meningocele, spina bifida, polycystic disease)

A. MALIGNANT NEOPLASMS

Etiology. There are many theories as to the etiology of malignant neoplasms, but it is generally admitted that the cause is still unknown. One of these theories is the *embryonal theory*, usually associated with the name of Cohnheim, who assumed that the tumor originated from an embryonic rest and that its malignant quality is simply the fetal power of growth carried into adult life. This undoubtedly applies to some congenital kidney tumors in childhood and perhaps to teratomas which become malignant. Another theory is that of *cell autonomy* which offers a conception of tissue tension that restrains growth. According to this theory, chronic irritation is one of the factors which enables certain cells to overcome this balance or restraint and allow rapid growth. Still another belief is that a malignant tumor is in reality an *infection*. For example, at least one type of experimental tumor, the Rous chicken sarcoma, is transmissible by a filterable agent, and is presumably of virus origin. At least two human tumors are of virus origin. In plants, a type of malignant growth has been associated with a complex protein molecule, the tobacco virus disease. The theory of an *inherited tendency* is now subject to intensive experimental and clinical study. In mice, its importance was thought to have been amply demonstrated, until the discovery of an agent in milk (Bittner, 3), the ingestion of which profoundly influenced the subsequent incidence of cancer of the breast in succeeding generations. This new factor has greatly increased the complexity of the factor of heredity. Nevertheless, a few types of neoplasms, such as polyposis of the colon and multiple osteocartilagenous exostoses, seem to have a definite hereditary tendency. Details of carcinogens and other etiologic factors will be found in the following chapter.

The greatest recent advance in research as to the cause of cancer is the discovery that certain chemicals (e.g., hydrocarbons and sterols) will produce cancer when injected into rats and mice (4). Such chemicals are called carcinogens. They are not normally present in the body but are closely related to many compounds which are present (5). This important line of investigation furnishes a definite basis for a *chemical-metabolic theory* for the cause of cancer. The favorable influence of chemotherapy (6) on certain types of cancers lends support to this theory. The well-known effect of sex and adrenocortical hormones (7, 8, 9) on prostatic and breast cancer also points to some metabolic abnormality in cancer. The theory that *acute trauma* may cause cancer is of more practical than scientific importance. The evidence is conflicting, but the question arises more often in sarcoma, particularly bone sarcoma, than carcinoma.

A history of trauma is so frequently given in various diseases that its relationship is always open to suspicion. Nevertheless, the matter has medicolegal importance, for courts have, on occasion, recognized such a relationship and have awarded large compensation claims even though scientific evidence in its favor is almost completely lacking.

Malignant disease is serious because it is a frequent cause of death (ranking second to heart disease), and cure is impossible without early diagnosis and adequate treatment. Another serious feature is that the recorded incidence of malignant disease is apparently on the increase (10), having doubled during the past 40 years. This increased frequency may not be a cause for alarm since part of this is undoubtedly due to improvement in diagnostic accuracy (11). Moreover, greater numbers of persons now attain the age when cancer is prevalent. In the United States, 60 per cent of cancer deaths are in patients over 45 years of age. In New York City, the proportion of persons over 45 is one third greater than a generation ago.

Clinical Characteristics. The earlier the lesion, the more difficult it is to make a diagnosis of cancer. It should be emphasized, however, that with thorough general and perhaps special examinations, the detection of cancer in its early stages is possible. The clinical manifestations of malignant disease depend of course on its site. Certain general characteristics, however, may be described, although most of them are obvious *only in the visible (i.e., external) types of cancer.*

(*a*) *Continued or progressive growth*, as well as progression of symptoms, is an important feature. Malignant tumors in most instances grow without interruption, whereas benign tumors stop growing after attaining a certain size.

(*b*) Local recurrence (or really local persistence) follows incomplete removal of a malignant tumor *but sometimes also of some benign tumors.*

(*c*) Metastasis is the most characteristic feature of cancer and is usually the most important factor in the fatal outcome. Metastasis is the spread of the growth, usually by way of the lymphatics or blood vessels, to regional lymph nodes and distant organs (*as the liver, lung, brain*). *Enlargement of lymph nodes* adjacent to an ulcerating carcinoma, however, may be due entirely to secondary infection and not to metastasis. Although metastasis is usually assumed to occur only by way of the lymphatics and the systemic and portal veins, an additional mode of spread has been postulated by Batson (1940), who has presented evidence that the system of vertebral veins (overlying the lumbar and thoracic vertebrae) plays an important role in metastasis. *Such channels would explain, for example, how metastasis to a vertebra might develop secondary to an abdominal cancer without involvement of the lung and without transmission through the lung.* According to Batson, the cancer cells are forced into the involved areas through the vertebral veins and collaterals by sudden changes in pressure. The various mechanisms of spread of carcinoma by implantation, venous emboli, and the like, are described in detail in Chapter 21.

(*d*) Local invasion by contiguity is another manifestation of most malignant tumors and may lead to much tissue destruction. *This invasive property resembles that exhibited by certain types of infection.*

(*e*) Hardness or firmness is an important diagnostic feature of most types of cancer, but is obviously of bedside value only when the tumor can be felt, as in the breast, rectum, mouth, or skin. This hardness is usually produced by excessive fibrous tissue which, however, varies greatly in different tumors. A sarcoma, for example, is apt to be *so cellular and vascular that it will have a soft consistency; scirrhous cancer, on the other hand, contains so much* fibrous tissue that it is often stony hard.

(*f*) Carcinoma, in general, is a disease of later adult life though not infrequent in those below 40 years of age. Sarcoma, on the other hand, respects no age group.

(*g*) Ulceration is frequent *in cancer of epithelial surfaces and, moreover, tends to progress (Fig. 1). In the* skin and mucous membranes, the edges of the ulcer are elevated, hard, and firmly elastic. Cancer of the mucous surfaces is especially prone to ulcerate, e.g., carcinoma of the stomach, *colon*, cervix, bronchus, lip, and tongue.

(*h*) *Bleeding is only occasionally encountered in the superficial malignant lesions of* the skin, but is frequent in carcinoma of the

Fig. 1. Extensive ulceration and bleeding in a far advanced fungating carcinoma of the neck.

colon, stomach, cervix, and bladder. The hemorrhage, though slight, is apt to persist and on many occasions leads to an insidious increasing secondary anemia.

(*i*) Disability as a characteristic of cancer is not of diagnostic importance since it occurs late and may be caused by any tumor or any type of inflammation. Cachexia and asthenia are present only in the terminal stage of cancer and are due, at least in part, to such effects of ulceration as bleeding and secondary infection. This is of practical importance because, in some instances, removal of an ulcerating cancer for its symptomatic relief may be justified even though the tumor has already metastasized and there is no hope of complete removal and cure. Cachexia and weakness, when present without ulceration, were formerly taken to indicate that the cancer may act as a true parasite, growing within and ultimately destroying its host. While this is probably true when the tumor involves vital functions or has metastasized widely, it is now recognized that starvation is frequently the basis for cancer cachexia, especially with ulcerating lesions. Starvation in cancer, in the presence of normal gastrointestinal function, is due to anorexia and can often be controlled, if indicated, by special methods to increase the nutritional intake (see Ch. 9). Pain as a symptom of cancer is present only in the terminal stages of the disease, except when the tumor irritates nerve endings by pressure or invasion or is growing rapidly in dense structures such as bone. The absence of pain in the early stages of many cancers is, of course, unfortunate because it increases the difficulty of early diagnosis.

(*j*) A fatal outcome of cancer is inevitable unless the entire tumor is completely removed or destroyed. Although, as emphasized by Everson and Cole (12), spontaneous cures have undoubtedly occurred, they are too rare to be of significance in diagnosis and treatment. Variations in duration are not uncommon, especially in the aged.

(*k*) Sensitivity to x-ray and radium is a characteristic of malignant disease which is very important in therapy; however, certain benign neoplasms share this sensitivity.

Microscopic Features. Because clinical diagnosis is often difficult it frequently becomes necessary to resort to microscopic examination of the suspected lesion. Such a procedure is called a biopsy; the tissue removed may consist of a part of the primary neoplasm or of a metastatic nodule. Biopsy of the original lesion should include normal as well as abnormal tissue in one piece so that the transition between the two can be studied. Serous effusions due to malignant disease may contain a sediment which will reveal cancer cells. Aspiration biopsy, which requires only a large needle, is an alternative method and may be

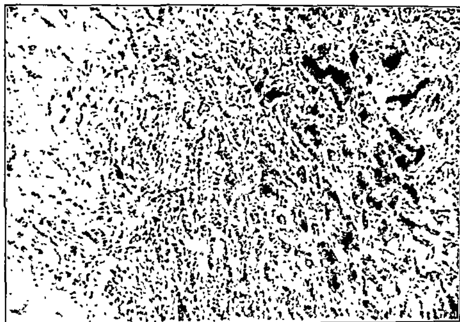

Fig. 2. Photomicrograph showing the invasive character of malignant disease. The microscopic section was taken from a carcinoma of the breast which had been removed surgically. Note the penetration of the strands of cancer cells through the fibrous stroma with no evidence of encapsulation or limitation.

used in certain patients, although it appears that this procedure may, at times, spread the disease.

The histological evidences of malignancy are as follows:

(*a*) *Abnormal cells,* more or less undifferentiated, even though growing in a form somewhat characteristic of the original tissue, are present. Nuclei stain more deeply and cytoplasm is more abundant.

(*b*) The growth is characteristically *invasive,* breaking through the normal tissue boundaries and extending into adjacent structures (Fig. 2).

(*c*) Rapid growth is often evinced by numerous *mitotic figures* and abnormally formed cells.

(*d*) The *fibrous tissue reaction* of the body to the tumor is sometimes very marked, especially in the so-called scirrhous type in which the intense fibrous tissue wall is formed presumably in an attempt to envelop and destroy the malignant cells. In rare instances this seems to have been achieved, since thorough search of the fibrosed tissue reveals few if any cancer cells. Such observations suggest the existence of a resistance on the part of the body to cancer.

(*e*) Attempts have been made to estimate the degree of malignancy by studying, more or less quantitatively, the above features of the cancer cells. Thus Broders has divided cancer into four arbitrary groups of malignancy, Types I, II, III, and IV, depending upon their histological features. While helpful in prognosis in certain cases, such histologic predictions are often inaccurate. The degree of malignancy is estimated with accuracy only by observing the clinical behavior of the growth.

Types of Malignant Disease. Malignant neoplasms are customarily divided into two groups, depending upon whether they originate from connective (mesodermal) or epithelial (ectodermal) tissue, although, as will be seen, this division is not absolute, for some tumors contain both types of cells. Occasionally it may be difficult to determine whether a neoplasm has originated from mesoderm or ectoderm. Ordinarily, however, this classification is fairly exact. The term *sarcoma* is applied to malignant tumors arising from mesoderm, i.e., fibrous tissue, cartilage, bone, fat, blood vessels, lymph tissue, and muscle, whereas *carcinoma* includes tumors of ectodermal or epithelial origin, i.e., skin, mucous membrane, liver, kidney, pancreas, and thyroid. There are certain other distinguishing features which separate sarcoma from carcinoma. Sarcoma, in general, is

bulky and soft, tends to remain demarcated, but grows rapidly along a vascular framework, often to great size, and is locally destructive. Notable exceptions are the hard osteosarcoma and some fibrosarcomas. Areas of hemorrhage, degeneration, and necrosis within the tumor are common. Sarcoma tends to break into blood vessels and metastasizes first to the lungs and later to other organs. Carcinoma, in general, grows more slowly but may metastasize when the tumor is small, first to the regional lymph nodes, then to the liver, lungs, bone, and so forth, by way of the blood stream; occasionally the reverse may be true. Originating from epithelial surfaces it is, of course, much more susceptible to ulceration and infection than sarcoma.

Treatment. Regardless of type, the general principles of curative cancer therapy are based on the eradication of *all* malignant cells. This eradication may be achieved (1) by surgical excision, (2) by destruction with radiotherapy and chemotherapy, or (3) by a combination of both. When cure cannot be hoped for, effective palliation is the secondary objective. The details of cancer therapy vary widely. The general principles are discussed in the next chapter.

I. Carcinoma. *Malignant tumors of epithelial origin may arise from the skin or mucous membranes or from glandular tissue such as the breast, prostate, colon, ovary, and thyroid. The term adenocarcinoma is used when the growth assumes an acinose form or originates from glandular tissue. When the tumor takes the form of a polyp or papilloma it may be called papillary carcinoma. The hard center of breast carcinoma with its lateral invading extensions suggested to Galen the appearance of a crab, hence its Latin equivalent, cancer.

1. CARCINOMA OF THE SKIN AND SQUAMOUS MUCOUS MEMBRANES. These carcinomas comprise (*a*) squamous cell, (*b*) basal cell, and (*c*) malignant melanoma. A fourth

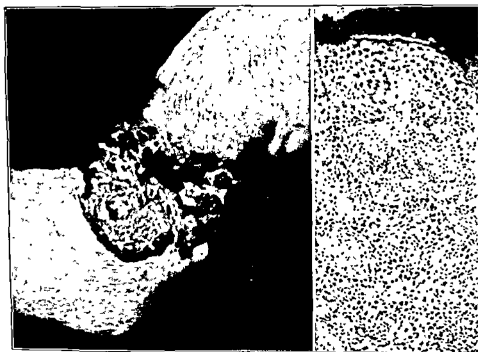

FIG. 3. Squamous cell carcinoma of the arm in an old ulcer (Marjolin's ulcer). The patient was an 80-year-old farmer who developed an ulcer which persisted following an injury 57 years previously. One year before admission a fungating growth developed at the site of the ulcer which grew steadily to the size shown in the illustration. Pain also developed and grew steadily worse. This represents the hypertropic type of squamous cell carcinoma and is of a relatively low degree of malignancy. The photomicrograph is from a biopsy specimen; note the extensive growth of squamous epithelium and the lymphocytic infiltration. Treatment in this type of tumor consists of wide local excision and the application of a skin graft to cover the defect; regional lymph nodes are also excised; occasionally amputation is indicated.

Fig. 4. Squamous cell carcinoma of the ear. In lesions of this type, resection of the major part of the ear is necessary; if the cervical nodes are involved, a radical neck dissection is also necessary.

type (*d*), Paget's disease of the nipple, is also included here because it starts as a skin lesion though it is always associated with or leads to adenocarcinoma of the breast. The term epithelioma is commonly applied to either the squamous cell or basal cell tumors of the skin, or collectively to both.

(*a*) *Squamous cell carcinoma.* This type occurs not only in the skin (Figs. 3, 4) but also in mucous membranes composed of squamous cells (buccal and genitourinary orifices). It also occurs at times by metaplasia from mucous membranes not normally composed of squamous cells, i.e., bronchus and gallbladder.

In the *skin,* it is most common in the head and neck, but it is prone to develop at the site of an old scar following a burn or extensive trauma (Marjolin's ulcer). Indeed, a previous lesion of some kind or a source of chronic irritation seems a common precursor of squamous cell carcinoma wherever its site. Males are more frequently affected than females (2:1). The growth takes one of two general forms, the papillary or the ulcerating type. The former is much less malignant and grows slowly as a cauliflower projection from the skin and metastasizes late. The ulcerating form is invasive, spreads rapidly, and metastasizes to the neighboring lymph nodes early. The edge is raised and indurated; the base is deep and bleeds easily. The ulcerative type is to be distinguished, however, from basal cell carcinoma which is described later.

In the *buccal cavity,* squamous cell carcinoma attacks the lip (Fig. 5), jaws, tongue, or pharynx. It affects males predominantly (5:1), but it is not a common lesion, accounting (with the skin) for but 6 per cent of malignant disease. As in the skin, previous lesions and chronic irritation in the buccal mucosa are frequent precursors of cancer. *Leukoplakia* is a common predisposing lesion which is said, in turn, to be associated with excessive use of tobacco and with syphilis. Leukoplakia is manifested as a whitish area in the mucosa of the borders of the tongue or lip, of a tough, leathery consistency, having a tendency in its later stages to become the site of fissures or ulceration. Microscopically,

Fig. 5. Squamous cell carcinoma in the lower lip. Verified by microscopic examination of a biopsy removed from the edge of the lesion.

Fig. 6. Leukoplakia. Photomicrograph from a section of a small white elevated area removed from the inner side of the patient's cheek. Note the hyperplasia of the keratin layer and the characteristic lymphoid infiltration and follicle formation just beneath the epidermis. This lesion is definitely a precursor of squamous cell carcinoma, and total removal is generally indicated.

the lesion consists of a proliferation of the outer squamous cell layers (Fig. 6). Other predisposing lesions are fissures of the lip, herpetic ulcers which do not heal, ulcers at the site of sharp teeth or dental appliances, and inflammation due to the prolonged use of pipes. Years ago, syphilis was said to be associated etiologically with carcinoma of the mouth but, apart from causing leukoplakia, such a theory is not tenable. As in the skin, two broad forms are distinguished clinically: the hard, ulcerating type and the soft, cauliflower or papillary type. In the lip, squamous cell cancer commonly attacks the lower lip. The ulcer is characteristic with a raised, indurated edge but may be flat and grow slowly, and seem to heal over in its less malignant form. Metastases occur to the cervical nodes which become enlarged; enlarged nodes, however, may be due to infection and not to cancerous invasion. Chancre of the lip may be mistaken for carcinoma, although the history, its short duration, and early involvement of lymph nodes should point to chancre. The finding of spirochetes in the discharge by darkfield illumination will establish the diagnosis of chancre and is of obvious importance.

In the *tongue, jaws, and pharynx,* carcinoma also presents a characteristic appearance, but occasionally is detected only by careful search (Fig. 7). Patients are usually aware of lesions in the mouth regardless of their characteristics (*13*). If in the cancer

Fig. 7. Squamous cell carcinoma of the tongue. Diagnosis was verified by microscopic examination of a biopsy specimen. The lesion, apparently of one year's duration in a 45-year-old male, disappeared after local radium treatment; a regional lymph node (neck) dissection was also carried out. Some surgeons prefer to completely excise the primary lesion when feasible.

Fig. 8. Basal cell carcinoma. The lesion started as a tiny "pimple" several months previously; the patient was a 65-year-old male. Entire lesion was excised and the wound closed by primary suture; healing was prompt and permanent.

age, they should be taught to have such lesions investigated. Pain, salivation, and hemorrhage are generally present only in the later stages. Dentists frequently see such lesions first. In the deeper recesses of the buccal cavity, especially the larynx, carcinoma is frequently unsuspected until such symptoms as hoarseness, bleeding, or, in some instances, cervical metastases occur. In the antrum, carcinoma is rare.

Treatment of squamous cell carcinoma of the skin and buccal mucosa first of all should be directed at the detection and treatment of the predisposing lesions which have been already mentioned. If doubt exists as to the nature of a chronic lesion, excision and mi-

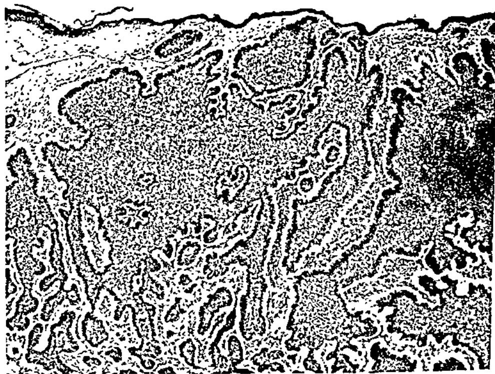

Fig. 9. Photomicrograph of basal cell carcinoma. This patient was a man, aged 69, who stated a small "sore" developed on the side of the nose and gradually grew; it bled readily and frequently. Because of neglect it was nearly 2 cm. in diameter and required resection of so much tissue that a sliding skin flap was required for closure.

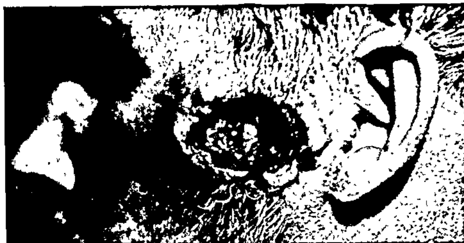

Fig. 10. Basal cell carcinoma of the face. The patient had submitted to improper treatment by the application of a "cancer paste" for several weeks. Note that the central portion of the lesion was destroyed at least in part, but the tumor at the edges is growing very actively. Radiotherapy is now being used.

croscopic section should be made. Destruction of such lesions is less advisable since it eliminates the opportunity for histologic study. There are two accepted methods of treating carcinoma of the buccal cavity. Many surgeons prefer wide excision of the lesion with bloc (neck) dissection of the regional lymph nodes. Other surgeons favor x-ray or radium therapy; combination of surgery and radiation may be used.

In the other orifices containing squamous cells, namely, the *genital* and *urinary* openings, cancer is also relatively easy to detect early, because the surface involved can be inspected and the lesion seen. In the bladder this requires a cystoscope, but in the cervix merely a speculum. Very important is detection of cancer of the female generative organs, since carcinoma of the cervix and uterus alone constitute 14 per cent of all malignant disease. The symptoms which should direct attention to such lesions are few. Abnormal bleeding, even though slight in amount, should always warrant an examination. Further discussion will be found in later chapters.

(*b*) *Basal Cell Carcinoma* (*Rodent or Jacob's Ulcer*). This carcinoma is most common on the face (Figs. 8, 9) and neck where it slowly invades the adjacent skin and underlying structures, although it practically never metastasizes. In rare instances it may arise in the skin of other regions, such as the legs, perineum, and upper chest wall. Basal cell carcinoma is a common disease in older persons and is frequently seen at a site of chronic irritation. Chronic exposure to the elements predisposes to its occurrence, hence its frequency in farmers. Basal cell carcinoma starts as a smooth nodule in the skin, then grows in size, and eventually breaks down in the center giving rise to an ulcer whose edges are elevated, indurated, nodular, and present a characteristic pearly appearance. The base is apt to be shallow, fibrotic, and covered with pale granulations. The ulcer progresses in size, but advanced cases with extensive destruction of tissue are rarely seen at the present time because adequate early treatment is so generally used and effective. Radiation (basal-cell carcinomas are among the most radiosensitive tumors), excision, or local destruction by cautery is curative. However, unless completely removed or destroyed, the growth recurs at an increased rate (Fig. 10).

(*c*) *Malignant Melanoma* (*Melanoblastoma, Chromatophoroma*). This carcinoma is a special form of malignant tumor of the skin arising in a mole (Fig. 11). The term melanoma is applied to tumors containing melanin, a brownish black pigment; melanomas may be malignant or benign. The benign type is discussed on page 418. Opinions differ as to whether malignant melanomas are of ectodermal or mesodermal origin; hence the term melanosarcoma, as well as melanocarcinoma, is often used.

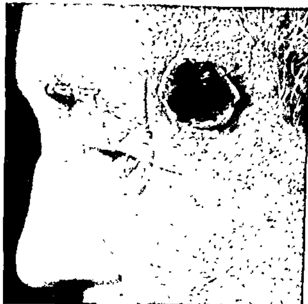

Fig. 11. Malignant melanoma. This lesion started as a small "pimple" eight months previously. Melanomas in this location are associated with a poor prognosis.

The retina of the eye, which contains the pigmented cells, is also a source of the neoplasm; however, melanomas in this location are surprisingly mild insofar as the five-year survival following enucleation of the eye is about 50 per cent. The disease is often very malignant, but in some cases many years may elapse between apparent successful removal of a primary growth and death from distant metastases which are rapid and widespread. The factors responsible for the prolonged inhibition of spread in such cases are unknown.

Metastasis may occur by way of the lymphatics (Fig. 12) or the blood stream. These tumors may be encountered at any age, are fairly common in young adults, but rarely indeed are found before puberty. It is important to remove moles which have a tendency to become malignant. It is obviously impracticable to remove all moles, but those subject to continued irritation should be excised since irritation is prone to provoke the malignant change. It is important especially to remove moles on the head and feet since those areas are the most frequent sites of the initial lesion of malignant melanoma. Any mole which exhibits sudden growth or bleeds without sufficient provocation should also be excised. If the mole shows microscopic evidence of malignancy the regional lymph nodes should be removed. Fortunately, malignant melanoma is a rare disease. It should be mentioned that occasionally nonpigmented moles undergo malignant change.

Malignant melanomas are much less vicious than generally considered, particularly if proper treatment—i.e., wide excision with radical resection of lymph nodes (even *though no nodes are palpable)*—is carried out. For example, in their experience with over 1,000 cases, Pack and associates (14) report a five-year survival rate of 14.1 per cent in patients with metastases to lymph nodes and 40.5 per cent in patients without metastases. In a study made by Booher and Pack (15) of all the melanoma patients seen at the Memorial Cancer Center, 16.5 per cent of the melanomas were located on the feet and hands. In patients having groin dissection (for melanoma on the lower extremity) without clinical or microscopic evidence of nodal metastases, the five-year survival rate was 40 per cent compared with 20 per cent if nodal metastases were present. The over-all salvage rate (five-year survival) for melanoma of the hand was 40 per cent but only 20.7 per cent for subungual melanoma. In 107 cases, Meyer (16) reports a five-year survival rate of 51 per cent. He advises prophylactic node resection as well as radical operation when nodes are palpable; 28 per cent of patients diagnosed as having negative nodes in his series actually were positive when examined in the surgical pathology room.

(*d*) *Paget's Disease of the Nipple*. This is a specific disease of the epithelium of and surrounding the nipple of the breast which ultimately develops into or is in some way associated with carcinoma. It starts as an exfoliating dermatitis or eczema which *does not* heal. The carcinoma is a typical adenocarcinoma of the breast whose histologic relation to the changes in the skin remains unestablished, though clinically the one seems to follow the other rather definitely. As a matter of *clinical practice any chronic dermatitis* of the nipple should be examined at frequent intervals; if it responds to local treatment and heals, as most cases of dermatitis do, the lesion is benign. If it does not heal and the patient is in the cancer age, operation is indicated (17) (see also Chapter 35).

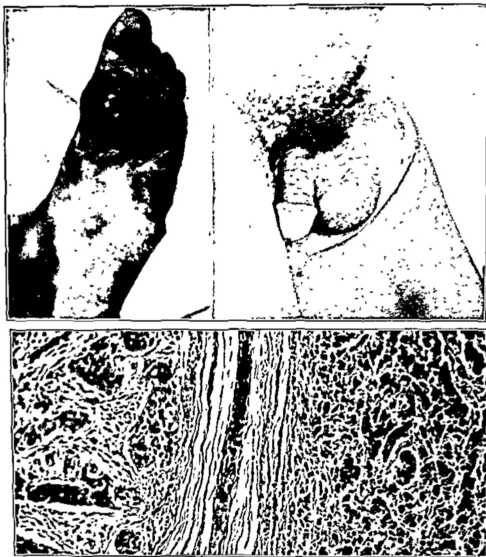

Fig. 12. Malignant melanoma. The course was rapidly fatal. The patient was a 45-year-old Negro; however, this type of cancer is relatively rare in the Negro race. The lesion started under the ball of the foot as a callus which the patient pared repeatedly. Rapid growth occurred during the past six months and a mass appeared in the groin. The photo shows the primary lesion in the foot and the metastasis in the regional (femoral) nodes. Death occurred one week later; autopsy revealed widespread metastases. The photomicrograph shows malignant cells both with and without the melanin pigment.

2. Carcinoma of Glandular Origin. This group is by far the largest and comprises most of the other epithelial malignant tumors (Fig. 13). The malignant cells usually assume the form of acini, rosets, or alveoli. Occasionally they are arranged in cords of cells. Other variations are also described. *Scirrhus* is a term which is applied to that type of cancer marked by fibrosis in and around the tumor as if the defense mechanisms of the body were trying to strangle the cancer. *Medullary (encephaloid) carcinoma* is a term applied to a soft, bulky tumor composed largely of cancer cells with very little associated fibrosis. *Colloid carcinoma* refers to tumors arising from mucous glands or to the growths which produce a great deal of mucoid material, visible grossly or microscopically. *Colloid* is found in cancer of the breast, stomach, and colon. When the cells take the form of acini, the term used is *adenocarcinoma*. These tumors may arise from either the secreting glandular cells or from the cells lining the ducts. Detailed discussions of glandular

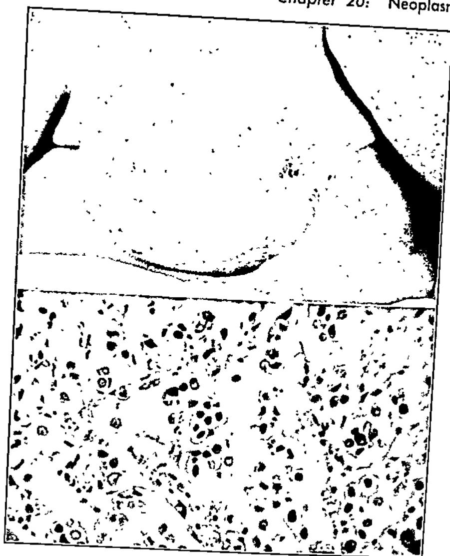

Fig. 13. Carcinoma of the breast of "low" malignancy. Note the retraction or puckered appearance of the skin over the lesion which was observed during a routine examination. The patient, aged 80, had been admitted to the medical ward because of severe hypertension; she claimed that the breast tumor had been present for 10 years. It was observed for three more years without any appreciable change. The photomicrograph was obtained from the specimen which was removed at autopsy when the patient died of cardiac disease. This represents a very slowly growing, almost benign, type of carcinoma and is, of course, unusual; it is of importance to note, however, that the microscopic appearance of the lesion gives very little indication of this characteristic This illustrates how misleading the "grading" of carcinoma may be when based on microscopic examination alone.

carcinoma will be found under the descriptions of diseases of the individual organs.

3. Miscellaneous Carcinomas. There are other carcinomas of miscellaneous types which are difficult to classify under a single designation. These tumors include hypernephroma, metaplastic neoplasms of the lung, and malignant teratomas, and will be discussed under the various organs affected. *Carcinoid* is a term applied to tumors which may occur anywhere in the gastrointestinal tract, most commonly in the appendix (see p. 760) but occasionally in the ileum. They are usually localized and benign but may sometimes become malignant and metastasize to lymph nodes, rarely elsewhere. Removal of the primary and the involved lymph nodes is almost always curative. The presence of serotonin metabolites (18) in the urine may be helpful in making the diagnosis.

II. Sarcoma. Sarcoma is less common than carcinoma, comprising but 3.5 per cent of all malignant tumors. It may develop wherever mesodermal tissue cells are present or grow from pre-existing benign tumors which are thus said to undergo "sarcomatous degenera-

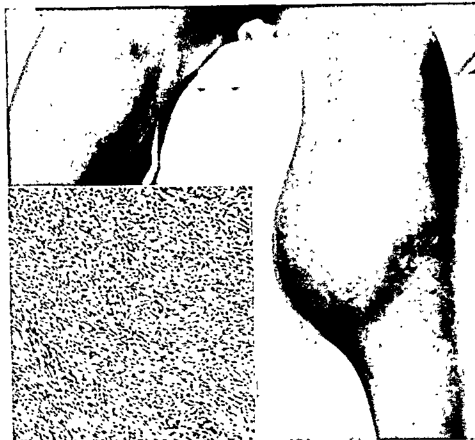

Fig. 14. Fibrosarcoma of the left leg. The patient, a 19-year-old Negro girl, first noted a swelling a year before admission; growth was rapid. In spite of amputation, pulmonary metastases occurred and the patient died six months later. The insert is a photomicrograph of the tumor and shows the undifferentiated spindle cell growth; there is less intercellular material than occurs in the more benign type of fibrosarcoma shown in Figure 15.

tion." The terms *spindle cell, round cell,* and *giant cell sarcoma* are histologically descriptive, but they do not indicate from which mesodermal element the tumor arises. To designate the exact tissue of origin the terms *fibrosarcoma, liposarcoma,* and *osteosarcoma* are used. In some instances, the histologic appearance of the tumor indicates its cell of origin. In many cases, however, this may be impossible to detect, especially when the growth is composed entirely of small or large round cells, although round cell sarcoma is ordinarily of lymphoid origin. Regardless of their microscopic appearance, the gross clinical manifestations as mentioned previously are fairly distinctive. The tumor when soft is often mistaken for a hematoma, an abscess (tenderness may be present) aneurysm, lipoma, or fibroma. With a large aspirating needle one is sometimes able to obtain a sufficient amount of tissue for microscopical study, although an actual biopsy is usually preferable.

Although no classification is entirely satisfactory, the various kinds of sarcoma may be most simply divided into 1. spindle cell (fibroblastic) sarcoma; 2. sarcoma of bone, and 3. round cell (lymphogenous) sarcoma. To this may be added 4. a small group of miscellaneous sarcomas, most of which are very rare.

1. Fibrosarcoma (Fibroblastic or Spindle Cell Sarcoma). *This tumor represents the most common type of sarcoma and is encountered chiefly in the subcutaneous and submucous tissue, the fascia, intermuscular septums, periosteum, and also in parenchymatous organs (Fig. 14). The size, consistency, and rate of growth vary greatly. Histologically, the cells are arranged in whorls of spindle cells which resemble fusiform fibro-

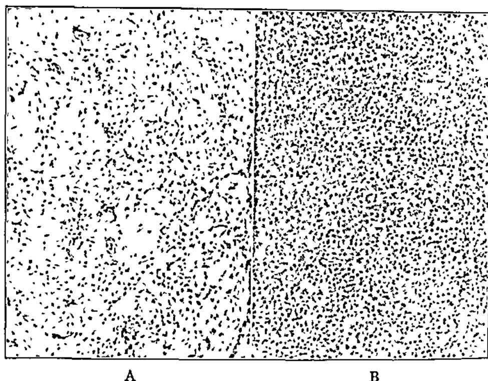

Fig. 15. Myxosarcoma, a more benign type of fibrosarcoma. A slowly growing tumor of the thigh in a male, aged 50, was excised three times during the course of six years because of recurrence. The photomicrographs are both from the tumor removed at the last operation; a fatal outcome several months later was due to widespread metastases. A, histologic appearance of a typical myxosarcoma, quite similar to that noted in the original tumor; B, this appearance was noted but a few millimeters away on the same slide as that of A; it shows a more cellular phase of tumor growth which is characteristic of this lesion whenever it develops increased malignant tendencies.

blasts and which may be either large or small. Because of their arrangement around the arteries they often seem to arise from the adventitial cells of the blood vessels. When they are present in the thigh, which is a frequent site, the tumor is bulky and has a tendency to local mucoid degeneration. When the entire tumor contains mucoid material it may be spoken of as *myxosarcoma*. It grows slowly, is prone to recur after excision, is not apt to metastasize, but is nevertheless usually fatal often because of a change in its cell type (Fig. 15).

Fibrosarcoma is seen early only when it appears near the surface of the skin. Though it may seem to be a fibroma grossly, a histologic diagnosis of sarcoma can be readily made and, of course, calls for wide excision. Fibrosarcoma usually grows rapidly but produces few symptoms until a large size is attained. Clinical manifestations are due to pressure of the tumor on adjacent structures. More often its size alone is the only complaint. Treatment consists of complete and wide excision, removing all the malignant tissue. Recurrence, however, is common; in the relatively benign myxosarcoma careful but wider excision of the recurrent tumors will be necessary. However, amputation may be indicated in the more malignant types of myxosarcoma when the tumor is in an extremity. Occasionally the tumor grows so rapidly that death occurs from metastases, particularly to the lungs, regardless of therapy. Other types of sarcomas, fibroblastic in origin, are occasionally found in the esophagus, stomach, intestine, uterus, ovary, and other organs, where they produce special symptoms dependent upon their location and may exhibit special and unusual microscopic features.

2. Bone Sarcoma. Probably because it is a rather rare tumor (1 per cent of all malignant lesions), bone sarcoma has long been a source of confusion because it produces a great variety of clinical, roentgenologic and histologic manifestations (Fig. 16). In order to recognize primary sarcoma of bone it is

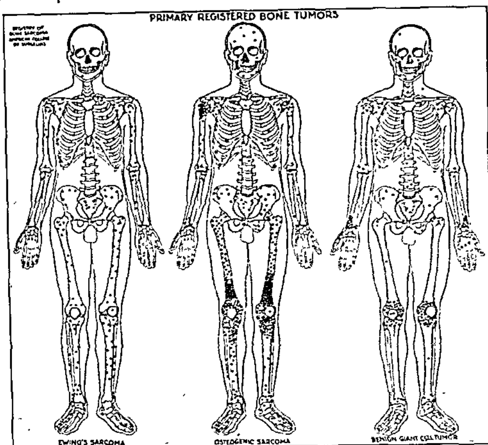

Fig. 16. Distribution of primary bone tumors. Note that the region of the knee is the most frequent site for osteogenic sarcoma. (From the Bull. Am. Coll. Surg.)

useful to realize that other bone lesions simulate it. In surveying these various bone diseases, one must distinguish the 1. malignant neoplasms which are not primary, i.e., carcinomas which have metastasized to bone from a focus elsewhere; 2. the group of true neoplasms of bone which are benign, particularly the giant cell tumor; and 3. the other diseases, inflammatory and metabolic, which simulate bone tumors.

Metastatic carcinoma to bone, the first group, is statistically important because of its frequency. Common clinical manifestations are pain, swelling, and spontaneous (pathologic) fractures. Occasionally, these lesions are the first intimation of disease, the primary focus remaining occult. The roentgenogram reveals bone destruction often described as having a "moth-eaten" appearance (Fig. 17), although in other instances there are areas of increased density simulating new bone formation. Of the *benign bone neoplasms,* giant cell tumor is most frequently a source of difficulty in diagnosis; these lesions are discussed further on page 408. Of the *inflammatory and metabolic diseases* of bone which are confusing, osteomyelitis is perhaps the most important, especially in differentiating from Ewing's tumor. These lesions are described in Chapter 24.

The classification within the group of true primary bone sarcoma also offers considerable difficulty, particularly in regard to the histologic appearance and pathogenesis of the various types. For this reason, no attempt will be made to distinguish, e.g., between those arising from cartilage and from bone, those which destroy or form bone, and those which are central, subperiosteal, or periosteal.

(*a*) *Osteogenic Sarcoma.* The term "osteogenic sarcoma," first used by Ewing, refers only to sarcoma originating in bone and must not be confused with the same term used to imply a sarcoma which forms bone (in con-

Fig. 17. Metastatic carcinoma in the skull arising from a primary (bronchiogenic) carcinoma of the lung.

trast to osteolytic sarcoma which destroys bone). Actually both bone destruction and bone formation may occur and is, of course, extremely important roentgenologically.

Clinical features of osteogenic sarcoma are usually distinctive. It is a tumor of adolescence, 50 per cent occurring in the second decade of life during which normal bone growth is most active. Moreover, 72 per cent occur in the lower extremity and of these 82 per cent are about the knee. They start at the end of the bone near the epiphysis (Fig. 18). The most important manifestation is pain, which precedes the appearance of the tumor and is severe and persistent. Such pain, when it develops in the long bones of the young adult, should always arouse the suspicion of bone sarcoma. The significance of trauma, though of great medicolegal importance, is questionable clinically; there is no evidence that trauma has etiologic significance. The swelling is slight at first but in neglected cases is characteristic, exhibiting a dusky hyperemia and often numerous dilated veins in the overlying skin. Local tenderness may be present, but on palpation the tumor will be hard and firm. Systemic manifestations are usually absent in this tumor. In some instances, where the tumor is near a joint, the signs and symptoms suggest a clinical diagnosis of arthritis and treatment for this condition is erroneously instituted.

Diagnosis is often aided by two procedures: x-ray and biopsy. The roentgenogram may be characteristic but is often equivocal. Both lytic and blastic processes are evident though one or the other predominates. The so-called "sun-ray" picture is usually pathognomonic but is not frequently observed. Adequate biopsy should be performed wherever possible to establish the correct diagnosis. This procedure is not easy in the case of malignant bone tumors as the surgeon too frequently removes overlying compressed tissue about the tumor and not portions of the neoplasm itself.

Treatment consists of operation or radiotherapy or a combination of both. Surgery may be either conservative (resection) or radical (amputation). Although "cure" is obtained only in a minority of cases (15 to 20 per cent), the surgeon aims to prolong life as much as possible and to ensure the comfort of the patient. When the tumor appears relatively small and has not perforated the overlying periosteum, most surgeons are reasonably conservative concerning amputation, insofar as they tend to resort to resection and bone graft with radiotherapy whenever local resection is possible. However, on many occasions local resection will be impossible, and amputation is the only hope of a cure.

(*b*) *Ewing's Sarcoma.* This neoplasm is relatively rare, comprising less than 10 per

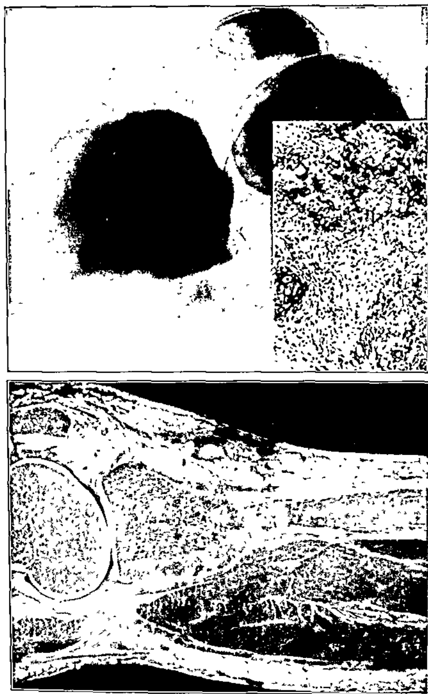

Fig. 18. Osteogenic sarcoma of the tibia. The patient was an 18-year-old boy. There was a history of trauma several weeks before the onset of a continuous ache which antedated the appearance of the swelling by two weeks. Swelling increased rapidly for six weeks before operation; a mid-thigh amputation was performed. The x-ray film shows a suggestive "sun-ray" effect; the lower photograph represents a longitudinal section of the amputated leg and shows the destructive process in the upper end of the tibia. The insert is a photomicrograph which shows malignant cells forming bone.

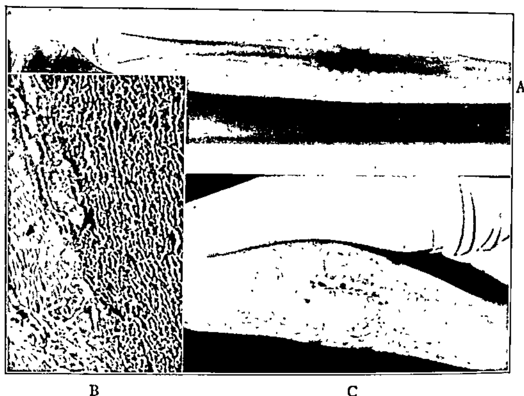

Fig. 19. Ewing tumor of the fibula. The patient was a 12-year-old boy. There was a history of swelling of the calf, and pain of four months' duration. A, x-ray on admission; note the location of the lesion in the center of the shaft and the "onion peel" appearance above and below the central portion of the tumor. B, photomicrograph of biopsy which confirmed the x-ray diagnosis; note the lymphoid character of the tumor invading the adjacent stroma. C, photograph of the leg one month later, following radiotherapy. Death followed within a year.

cent of all bone sarcomas; more than half are seen in children between the ages of 6 and 15 years. It originates as a small round cell tumor resembling lymphosarcoma, probably from lymphatic channels within the cortex, but produces pronounced bone changes (Fig. 19). Unlike osteogenic sarcoma, it attacks the shaft rather than the end of the bone. Another characteristic of Ewing's sarcoma is that it metastasizes to the other bones as well as to the lungs. Clinically, pain is apt to occur in attacks and is usually preceded by trauma. Systemic manifestations of fever and leukocytosis, as well as local tenderness, often lead to a suspicion of osteomyelitis. Roentgenograms are often diagnostic because the tumor is located in the intracortical part of the shaft and also because the so-called "onion-peel" and "sun-burst" appearance is sometimes present. Treatment is that of osteogenic sarcoma. Immediate response to x-ray therapy characterizes this group of neoplasms.

(c) *Myeloma.* This is even more rare, occurs mostly in middle and advanced age, and is manifested by rheumatic pain and skeletal deformities in advanced stages. Spontaneous fractures, most often in the ribs, are frequent. The common histologic type is characterized by large plasma cells; less frequently, the type of cell consists of a myeloblast. Roentgenograms show multiple "punched-out" areas; between 50 and 75 per cent show Bence-Jones proteinuria. All cases are fatal in about two years. Treatment is symptomatic, x-ray often alleviating the pain.

(d) *Unclassified Sarcoma.* In this final group are placed two tumors—angioendothelioma and extraperiosteal sarcoma of bone. The first is extremely rare and presents the same diagnostic and therapeutic problem as osteogenic sarcoma; it is described separately largely because of its peculiar histologic appearance. The second tumor is in reality no bone sarcoma at all, but a fibrosarcoma of the periosteum or adjacent fascial planes, and behaves and is treated as other fascial sarcoma. It may produce bone changes but only by pressure from without.

3. SARCOMA OF LYMPHOID TISSUE (MALIGNANT LYMPHOMA). Though essentially a round cell tumor, this type may be classified, according to Ewing, into at least four groups. This division is largely arbitrary, however, since the cell of origin is not always known. Nevertheless, these tumors have the clinical features of malignancy and seem to arise from, or at least to involve, the lymph nodes primarily. Many of these lesions respond to anticancer agents, which is very useful, particularly in the lesions which are not amenable to surgery or radiation. The polyfunctional alkylating agents—e.g., nitrogen mustard, triethylenethiophosphoramide (thio-TEPA) and triethylenemelamine (TEM)—and numerous antimetabolites—e.g., 6-mercaptopurine and aminopterin—have been used in these lesions, often with satisfactory regression (19), although no cures have as yet been achieved.

(*a*) *Simple Lymphoma* (*Lymphadenoma, Hyperplastic Lymphadenitis*). This type, though histologically a benign and usually inflammatory enlargement of lymph nodes, is mentioned here because it sometimes presents difficulty in microscopic diagnosis. This becomes evident when the nodes persist, grow, and eventually cause death (Ewing). Subsequent study may show that they bear a relation to the other obvious malignant tumors of lymph nodes.

(*b*) *Leukemia.* Though a neoplasm of the blood forming cells, leukemia is included here because the lymph nodes are involved in the disease, regardless of whether the leukemia is of the lymphatic type or of the myelogenous type. The nodes are usually discrete, although when they are large they soon coalesce. The spleen is often enlarged. Blood examinations make the diagnosis, except in certain cases when there may be no leukocytosis (aleukemic leukemia). Excision of a node will reveal a microscopic picture which is characteristic. Treatment with intravenous injections of nitrogen mustard or of radioactive phosphorus is often effective. Deposits of lymphogenous or myelogenous cells are sometimes seen at other sites, including the skin (leukemia cutis). A greenish tumor of a leukemic type which may occur in the skull, vertebrae, and ribs is called *chloroma* and, curiously enough, appears now to have become almost extinct.

(*c*) *Hodgkin's Disease.* This is a malignant disease *involving the lymphatic system,* particularly the lymph nodes; it is manifested by progressive enlargement of the lymph nodes most frequently in the cervical region but also in the mediastinum and elsewhere; the disease is often associated with fever, anemia, and other blood changes. The enlarged nodes on microscopic section show a fairly characteristic hyperplastic picture upon which the diagnosis frequently depends (Fig. 20). Fibrosis of a diffuse nature is a constant finding but can be differentiated from that encountered in tuberculosis by the absence of necrosis and tubercles. Other features include the presence of numerous eosinophils and large multinucleated reticulum (Dorothy Reed) cells.

The disease is subject to much clinical variation; it is to some extent dependent upon the chain of nodes involved. In superficial locations, usually the cervical region, the individual nodes are palpable as discrete elastic masses, variable in size and not tender. The spleen is enlarged in over half the cases. X-ray may reveal enlargement of the mediastinal nodes; bone and skin involvement have been described. Generalized pruritis is said to be a frequent symptom at an early stage of the disease, the itching being due presumably to infiltration of the skin with lymphoid cells. Systemic symptoms may be absent; in some patients, on the other hand, high fever of the Pel-Epstein intermittent type and prostration develop. Changes in the white blood cells have been described but are frequently absent; eosinophilia and increase in the mononuclear cells of the blood, however, are often present and may be of diagnostic value. Anemia is sometimes severe and may require repeated transfusion. Radiotherapy and chemotherapy will cause temporary but usually rapid and complete regression of the enlarged nodes, although the course is usually downhill and death occurs after months or years from cachexia and anemia. A survival of over 20 years is shown in Figure 18, p. 611. When the disease is localized (i.e., without demonstrable metastases) in the neck or in any other operable site where radical resection is feasible, operation is indicated and

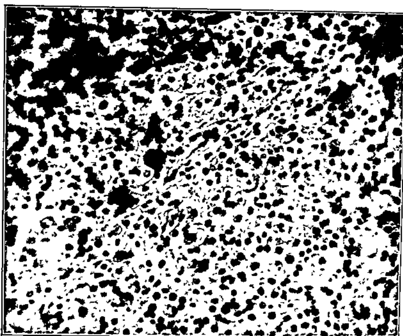

Fig. 20. Hodgkin's disease. Enlarged cervical nodes were observed three months before admission The photomicrograph is from a section of one of them which was excised for diagnosis. Note the characteristic multinucleated (Dorothy Reed) cell in the center of the field; many eosinophils are also present. Death occurred one and one-half years later with enlargement of the spleen, mediastinal and mesenteric nodes. Radiotherapy was refused by the family because the patient, a 37-year-old male, was a mental defective.

will be followed by very favorable results (20).

(*d*) *Lymphosarcoma* (*Lymphoblastoma, Lymphocytoma*). This sarcoma is a true primary neoplasm of the lymphoid tissue. Lymphoid tissue is, of course, distributed more or less throughout the human body but is especially concentrated in the lymph nodes. At the present time it seems probable that this lymphoid tissue has its origin in a syncytial type of undifferentiated supporting cell which has the power of producing the so-called lymphocyte as well as the reticuloendothelial cell. Tumors arising from these two cell types may sometimes resemble each other and make classification extremely difficult. As a rule, however, they differ in microscopic and clinical characteristics just as normally they differ as to structure and function. For purposes of classification, therefore, we have two types of lymphosarcoma—the lymphocytic and the reticular cell.

1. Lymphocytic lymphosarcoma is a primary tumor, the type cell of which tends to resemble the lymphocyte. The chief symptoms are those produced by the local enlargement of groups of discrete nodes, without local tenderness or general symptoms, although a low grade fever and weakness may at times be present (Fig. 21). Cachexia is absent. Microscopically, the lymph node loses its normal architecture and in its place one sees masses of abnormal lymphocytes growing at random with a minimum of reticulum and usually no germinal centers. While this cell is extremely sensitive to irradiation at first, it eventually becomes resistant, and the life expectancy in this disease is rarely over two years except in unusual cases. In the later stages of this type of lymphosarcoma, fixed lymphoid tissue in many parts of the body may become involved or the tumor may metastasize as does any other sarcoma. At such times the lungs and heart are frequently involved.

2. Reticulum cell sarcoma is a primary tumor, the cell type of which tends to resemble the reticuloendothelial cell. It involves most frequently the lymph nodes of the neck, axilla, mediastinum, and abdomen. As this same cell type is dominant in Hodgkin's disease, the lymph node enlargement may often resemble this condition. In fact, there are some authorities who prefer not to separate

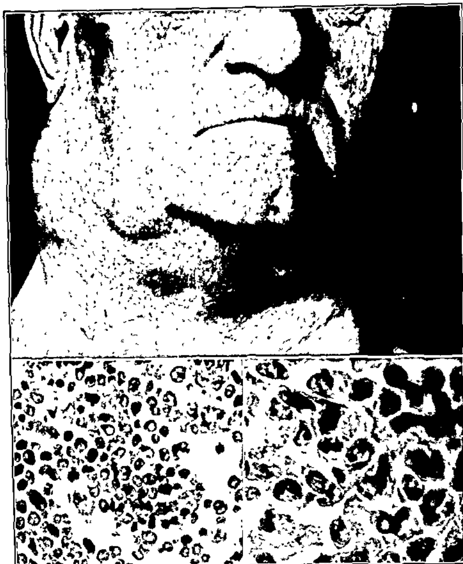

Fig. 21. Rapidly fatal lymphosarcoma. The patient was a 66-year-old man. The onset was only two and one-half months previously with a gradually increasing swelling of the neck and groin. At autopsy the nodes in the mediastinum and abdominal mesentery were also enlarged. Metastatic nodules were found in the lungs, kidney, and spleen. The low and high power photomicrographs show the histologic appearance of the cells.

the two diseases but rather to consider them as manifestations of the same fundamental disturbance. While at the onset the glands are generally discrete, there is a tendency toward coalescence during the later stages, giving clinical features not unlike those seen in certain types of exudative tuberculous lymphadenitis. The nodes are hard, not tender, and tend to remain local for a much longer period of time than does the lymphocytic type. Because of this act, local excision has at times been advocated and we have seen cases free from recurrence for a long period of time following this procedure. Recurrence does generally take place, however, along with involvement of other nodes and tissues. At this time, loss of weight is often seen and the picture becomes one of sarcomatous invasion. *Microscopically, the picture is that of* cells growing with an effort to form reticulum. The nucleus is large and vesicular and the cytoplasm abundant. Phagocytosis may even be observed in the slower growing types. Silver stains show a massive amount of reticulum.

Lymphosarcoma *may occur without obvi-*

ous involvement of lymph nodes. In such cases, the disease presents the clinical features of a localized neoplasm. For example, lymphosarcoma of the stomach is usually diagnosed as gastric cancer, yet has a relatively good prognosis. Since it affects the gastrointestinal tract in the small and large intestine and rectum, it seems to assume greater virulence.

4. MISCELLANEOUS SARCOMAS. Included under this heading are the following malignant growths of mesodermal origin: (*a*) *liposarcoma*, while rare, is a very malignant tumor with a rapidly fatal course, producing local and general metastases, especially to the lung. It is important to remove completely all lipomas, for they may, on rare occasions, harbor sarcomatous areas recognizable grossly as being very cellular and on section containing cells with only traces of fat. (*b*) *Rhabdomyosarcoma* are tumors of striated muscle which have become malignant. They are very rare. (*c*) *Thymoma* is a rather loosely used term to indicate a neoplasm involving the thymus. Many tumors in this region are really mediastinal lymphosarcoma. Tumors which involve the thymus primarily are quite rare; moreover, there is considerable dispute as to the histologic evidence of their origin.

III. Brain Tumors. Brain tumors are special neoplasms which are really difficult to classify. Many of them (gliomas) are of ectodermal origin; many, however, are really of uncertain origin. In many instances they produce death not by the usual means, i.e., metastasis, ulceration, cachexia, or wasting, but by virtue of their local effects on brain function and intracranial pressure. Some are benign in that they can be removed and the patient cured; others are malignant in the sense that they recur after removal, and continue to invade the brain tissue. Other brain tumors are metastatic from distant primary sites, especially from carcinoma of the lung. Consideration of these tumors belongs to the special field of brain surgery, and are discussed in Chapter 27. Details may be found in special publications (21, 22).

NEUROCYTOMA. This neurogenic tumor has general surgical interest because it occurs outside the brain and cord in the rich autonomic network of the posterior abdominal wall, producing a retroperitoneal tumor which causes symptoms by its size and by pressure on adjacent structures. Though malignant, and sometimes rapidly so, this neoplasm often responds dramatically to radiotherapy or even seems to disappear spontaneously. It is rather rare and simulates, even on microscopic section, other abdominal growths. A large percentage of these tumors are found in children. Other terms for neurocytoma are neuroblastoma, sympathicoblastoma, and so forth.

B. BENIGN NEOPLASMS

Unlike cancer, benign neoplasms grow to a limited size, do not metastasize, and in general are not fatal. A few are really not true neoplasms insofar as they result directly from irritative or inflammatory stimuli (keloid, clavus, cutaneous horn, and the like). The etiology of most benign tumors, however, is unknown except that some cellular stimulus to useless growth of this type must be present. Occasionally, the stimulus appears to be due to abnormal endocrine activity, particularly in the development of certain adenomas. The neoplastic change, though apparently different from that seen in cancer, may be of the same kind, but merely different in degree. Some benign tumors, moreover, have a malignant tendency insofar as they *recur* unless entirely removed. On rare occasions, benign tumors undergo spontaneous malignant changes, metastasize, and finally result in the death of the patient. It is possible, therefore, that when the cause of cancer is discovered one may also learn why benign tumors develop.

Like cancer, benign tumors may be classified into those arising from mesodermal and those arising from epithelial cells. However, it is clinically more useful to divide the benign neoplasms into seven groups depending upon the tissue of origin, regardless of its embryonic type.

I. Connective Tissue Origin. These neoplasms may be further classified into three subgroups: fibrous, fatty, and bone and cartilage tumors.

1. FIBROUS TISSUE TUMORS. Various in form and appearance, these neoplasms have in common a predominance of fibrous tissue on microscopic section. It will be recalled that this is, in fact, the microscopic charac-

Fig. 22. Keloids of typical appearance, both in Negroes. a, keloid at the site of a puncture for earrings; there was a history of considerable suppuration at the time the puncture was performed several months previously. b, this keloid formed at the site of a razor slash of the abdomen which had become infected and healed slowly.

teristic of the end stage of repair; scar tissue is nothing more than a mass of fibrous tissue. However, scar is distinguished from tumor by its inconspicuous size, i.e., though composed of the same tissue as a fibrous tissue tumor (fibroma), it is not large enough to be called a tumor. Sometimes, however, the deposition of scar is sufficiently large and conspicuous to be called a tumor; it is then called a keloid.

(*a*) *Keloid.* This neoplasm is in reality a fibroma that grows, however, only after a stimulus of injury which may be trivial, such as the puncture of an ear lobe for wearing earrings (Fig. 22). The demarcation between a normal scar and a keloid is inexact but depends largely on size. Other features of keloids are their tendency to form in Negros, their predilection for large granulating areas in which burns and severe suppuration have occurred, and their relative absence in clean, aseptic wounds which have healed without irritation. Though of considerable theoretical interest in wound healing and in their relation to neoplastic growth, keloids have a practical importance only when they become large or painful or when they are present over the face, neck, and arms, especially in young women. Excision is the treatment of choice, plus skin graft when the keloid is extensive. Radiotherapy has been disappointing.

(*b*) *Simple Fibroma.* This neoplasm is a circumscribed tumor arising spontaneously, anywhere in the body, but usually in the skin or subcutaneous tissue. When it occurs in the form of a papilloma, it is an ovoid tumor covered by skin or mucous membrane (Fig. 23), and attached by a thin stalk or pedicle. Fibroma, though it may consist entirely of fibrous tissue, is commonly associated with other mesodermal or epithelial elements and is therefore called lipofibroma, neurofibroma, adenofibroma, myofibroma, and so forth. Neurofibroma occurs in Recklinghausen's disease, which will be considered on page 410. When the cells in a fibroma have mucoid material between them, the tumor may

Fig. 23. Fibroma of the gum. This lesion started less than a year previously and grew rapidly. It was attached to the lateral portion of the gum on the upper jaw, with a relatively small stalk. It was removed without difficulty; prognosis is good.

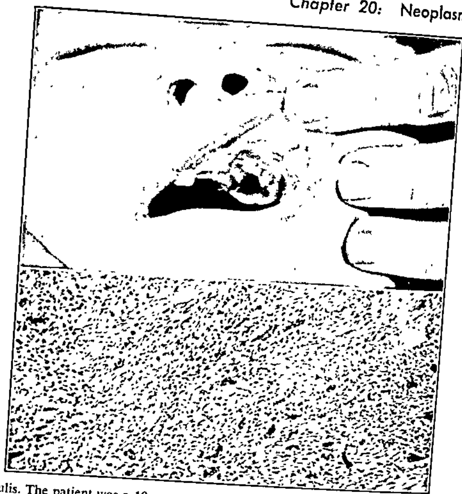

Fig. 24. Epulis. The patient was a 10-year-old girl. There was a history of an injury to the jaw before the onset of the tumor which was of two months' duration, growing slowly and bleeding occasionally. The insert is a photomicrograph of the excised tumor; note the numerous giant cells throughout the fibrous tissue stroma.

be spoken of as a *myxoma* or fibromyxoma. Many fibrous tumors which are soft contain myxomatous material. Certain small fibromas occur in the skin and become painful to the touch because of the presence of nerve fibers, though they are not true neurofibromas (see glomus tumors, p. 409). Treatment consists of excision when indicated. *Desmoid tumor* is a rare type of fibroma which originates from the fascial structures of the anterior abdominal wall, nearly always in women and in those who have borne children. While the tumor may sometimes contain cellular or myxomatous areas it is really a benign tumor, in spite of its tendency to recur after removal. Treatment consists of wide excision followed by adequate repair of the defect in the abdominal wall.

(*c*) *Epulis*. This is a name given to a fibroma (which often contains giant cells on microscopic section) arising from the portion of the gum which lines the submerged surface of the tooth (peridental membrane). It grows sometimes as a papilloma with the stalk attached to the gum at this point, but usually has a broad base and is expansile in its growth. It rarely grows to a large size, but recurs unless removed completely with a margin of normal gum tissue (Fig. 24). It is usually necessary to extract one or two teeth. In some instances sarcomatous changes have been observed.

(*d*) *Giant Cell Tumor*. This tumor, which is commonly found in the tendon sheaths and aponeuroses of the hands and feet, is a small fibroblastic neoplasm which contains giant cells. It is easily removed but tends to recur if not completely excised. Clinically it has no malignant tendencies, although it is occasionally spoken of as giant cell sarcoma largely because of its histologic appearance.

2. Fatty Tissue Tumors. There are but

Fig. 25. Lipoma of the arm and back. The lipoma on the arm has an unusually smooth outline, but the one on the lower left side of the back has the typical lobulated appearance. Both revealed a lobulated characteristic on palpation, less so on the arm.

two representatives in the group of fatty tissue tumors: the lipoma, which is common, and the xanthoma, which is rare.

(*a*) *Lipoma.* The lipoma is composed of normal fat cells or, at most, cells larger than normal, arranged in the form of lobules which may be large and few in number, or so multiple as to resemble a cluster of grapes. True lipomas are definitely delimited by the surrounding fibrous tissue which fits tightly around each of those lobules. Its most common sites are the subcutaneous tissues of the shoulders, back, upper arm, and buttocks, more frequently in obese individuals (Fig. 25). It has been found, however, in nearly every part of the body, including the pelvis, kidney, bone, and spinal cord. The tumor varies in size from that of a pea to that of a person's head. Its softness is a source of confusion to the novice, for it gives a sense of fluctuation which may lead to the diagnosis of a cyst or cold abscess. It may cause symptoms because of its size or cause pain by pressure on nerves. Treatment consists of excision which must be complete in order to prevent recurrence. A rare disease in obese individuals with multiple painful fatty tumors has been described by Dercum (adiposis dolorosa). Multiple subcutaneous lipomas may also occur and be associated with large accumulations of fat in the mesentery, palpable as an abdominal tumor.

Fig. 26. Osteochondroma. The location, as shown in the x-ray, is characteristic at the adductus tubercle of the femur. The patient was a nine-year-old boy. There was a history of injury to the knee which became "black and blue" at the site of a swelling noted by the mother. Operative excision was carried out; the diagnosis was confirmed microscopically.

(*b*) *Xanthoma*. The xanthoma, a rare tumor, may be single or multiple (xanthomatosis) and in the gross is yellow, hence the name. When the tumor is superficial, the color can be seen through the skin. Microscopically, it consists of foamy cells and, frequently, giant cells. The fat in the cells is composed of cholesterol and is supposed by some to represent a defect in cholesterol metabolism. These tumors may develop about the eyelids or joints or in tendon sheaths and are usually small. On rare occasions they are found in the ribs and cranium.

3. Bone and Cartilage Tumors. These tissues are conveniently considered together since they are frequently associated in the development of benign bone tumors. The tumors comprise five types.

(*a*) *Osteochondroma or Exostosis* (*Osteoma*). This is a common tumor, occurring most frequently near the ends of long bones, particularly at the distal end of the femur (Fig. 26). It arises, presumably, from misplaced cartilaginous tissue but consists primarily of bone. It produces no symptoms, often being noted accidentally in an x-ray film taken for another purpose. However, sometimes a mass is noticed; pain, when present, is more of an ache or discomfort. Occasionally a bursa forms over the tip of the tumor and may produce symptoms of bursitis when injured. Malignant changes may occur but only in persons over 30 years of age. Osteochondroma is most frequent in persons between 10 and 20 years of age. Roentgenologically, the tumor has a base of normal bone protruding through the periosteum, the tip of which is covered more or less completely by cartilage. If symptoms are present, excision, including a cuff of normal bone, is indicated. When noted in a person over 30 years of age, the possibility of malignant change should be borne in mind. Exostoses, when multiple, may have a pronounced hereditary tendency and other features. *Subungual exostosis* is a special variety of osteochondroma which grows under the nails of the fingers or toes where it may cause considerable pain and, by breaking through the skin, lead to secondary infection. Excision is usually indicated after infection, if present, has subsided.

(*b*) *Chondroma* (*Enchondroma*) or *Chondromyxoma*. This tumor is fairly common and, while it resembles the exostosis microscopically, it is a central tumor in contrast to osteochondroma, which is periosteal. It is most frequent in the phalanges (Fig. 27) of the hand or foot; it also is seen in the long bones, sternum (Fig. 28), and spine. It is only rarely multiple. The symptoms are those of swelling, tenderness, and pain. The larger tumors in the sternum and spine are prone to malignant change in that they are apt to recur and eventually to metastasize, unlike those appearing in the phalanges, which are more

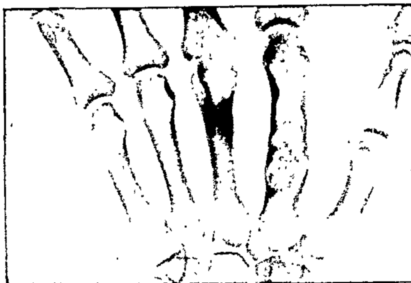

Fig. 27. Enchondroma of the second metacarpal. The patient was a 25-year-old machinist. The existence of the lesion was discovered only by x-ray, which was taken because the patient had a serious hand infection; a pyogenic arthritis with destruction of the articular cartilage of the third metacarpophalangeal joint can be clearly noted. No treatment was indicated for the enchondroma.

benign. Microscopically, the tumor contains fairly normal adult cartilage but grossly shows much gelatinous or myxomatous material. Roentgenologically, there is a translucent central area with thinning and expansion of the cortex. Unlike the osteochondroma, it contains no bone. It is the most common cause of central bone destruction in the phalanges (see Fig. 27). Though rare in the long bones, its x-ray appearance is similar to bone cyst or benign giant cell tumor. Treatment, when indicated because of pain or swelling, consists of thorough excision.

(*c*) *Bone Cyst.* The bone cyst is different from osteitis fibrosa cystica in that it is solitary, whereas the latter term implies multiple lesions. Bone cyst is most frequent in the upper humerus (Fig. 29), tibia, and femur. It is most common in children under 15 years of age, occasionally produces pain and evident swelling, but more commonly is noted in the x-ray because it becomes the site of fracture which may be of the "spontaneous" type, i.e., occurs following normal movements or with very slight trauma. The x-ray shows an expanding central defect with

Fig. 28. Recurrent enchondroma of the sternum. The original tumor was removed six months previous to the recurrence shown in the photograph. Though histologically similar to the tumor illustrated in Figure 27 this type is quite different in its clinical behavior. The photomicrograph is from a section of the original tumor and shows typical chondroblasts.

Fig. 26. Osteochondroma. The location, as shown in the x-ray, is characteristic at the adductus tubercle of the femur. The patient was a nine-year-old boy. There was a history of injury to the knee which became "black and blue" at the site of a swelling noted by the mother. Operative excision was carried out; the diagnosis was confirmed microscopically.

(*b*) *Xanthoma.* The xanthoma, a rare tumor, may be single or multiple (xanthomatosis) and in the gross is yellow, hence the name. When the tumor is superficial, the color can be seen through the skin. Microscopically, it consists of foamy cells and, frequently, giant cells. The fat in the cells is composed of cholesterol and is supposed by some to represent a defect in cholesterol metabolism. These tumors may develop about the eyelids or joints or in tendon sheaths and are usually small. On rare occasions they are found in the ribs and cranium.

3. Bone and Cartilage Tumors. These tissues are conveniently considered together since they are frequently associated in the development of benign bone tumors. The tumors comprise five types.

(*a*) *Osteochondroma or Exostosis* (*Osteoma*). This is a common tumor, occurring most frequently near the ends of long bones, particularly at the distal end of the femur (Fig. 26). It arises, presumably, from misplaced cartilaginous tissue but consists primarily of bone. It produces no symptoms, often being noted accidentally in an x-ray film taken for another purpose. However, sometimes a mass is noticed; pain, when present, is more of an ache or discomfort. Occasionally a bursa forms over the tip of the tumor and may produce symptoms of bursitis when injured. Malignant changes may occur but only in persons over 30 years of age. Osteochondroma is most frequent in persons between 10 and 20 years of age. Roentgenologically, the tumor has a base of normal bone protruding through the periosteum, the tip of which is covered more or less completely by cartilage. If symptoms are present, excision, including a cuff of normal bone, is indicated. When noted in a person over 30 years of age, the possibility of malignant change should be borne in mind. Exostoses, when multiple, may have a pronounced hereditary tendency and other features. *Subungual exostosis* is a special variety of osteochondroma which grows under the nails of the fingers or toes where it may cause considerable pain and, by breaking through the skin, lead to secondary infection. Excision is usually indicated after infection, if present, has subsided.

(*b*) *Chondroma* (*Enchondroma*) *or Chondromyxoma.* This tumor is fairly common and, while it resembles the exostosis microscopically, it is a central tumor in contrast to osteochondroma, which is periosteal. It is most frequent in the phalanges (Fig. 27) of the hand or foot; it also is seen in the long bones, sternum (Fig. 28), and spine. It is only rarely multiple. The symptoms are those of swelling, tenderness, and pain. The larger tumors in the sternum and spine are prone to malignant change in that they are apt to recur and eventually to metastasize, unlike those appearing in the phalanges, which are more

Fig. 27. Enchondroma of the second metacarpal. The patient was a 25-year-old machinist. The existence of the lesion was discovered only by x-ray, which was taken because the patient had a serious hand infection; a pyogenic arthritis with destruction of the articular cartilage of the third metacarpophalangeal joint can be clearly noted. No treatment was indicated for the enchondroma.

benign. Microscopically, the tumor contains fairly normal adult cartilage but grossly shows much gelatinous or myxomatous material. Roentgenologically, there is a translucent central area with thinning and expansion of the cortex. Unlike the osteochondroma, it contains no bone. It is the most common cause of central bone destruction in the phalanges (see Fig. 27). Though rare in the long bones, its x-ray appearance is similar to bone cyst or benign giant cell tumor. Treatment, when indicated because of pain or swelling, consists of thorough excision.

(*c*) *Bone Cyst.* The bone cyst is different from osteitis fibrosa cystica in that it is solitary, whereas the latter term implies multiple lesions. Bone cyst is most frequent in the upper humerus (Fig. 29), tibia, and femur. It is most common in children under 15 years of age, occasionally produces pain and evident swelling, but more commonly is noted in the x-ray because it becomes the site of fracture which may be of the "spontaneous" type, i.e., occurs following normal movements or with very slight trauma. The x-ray shows an expanding central defect with

Fig. 28. Recurrent enchondroma of the sternum. The original tumor was removed six months previous to the recurrence shown in the photograph. Though histologically similar to the tumor illustrated in Figure 27 this type is quite different in its clinical behavior. The photomicrograph is from a section of the original tumor and shows typical chondroblasts.

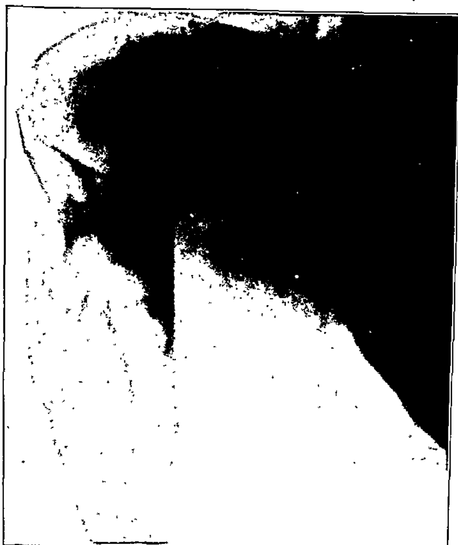

Fig. 29. Bone cyst. This is a solitary lesion as was shown by x-rays taken of many other bones. The lesion was noted because of the fracture which was sustained while the patient, a healthy 21-year-old male, was pitching a baseball. The fracture was treated just as if no cyst were present, and healed normally.

thinning of the cortex. The cavity contains clear or straw-colored fluid and is lined by cells showing fibrous tissue and some new bone formation. Phemister has presented evidence that the lesion is inflammatory in origin. Treatment in case of fracture is the same as if the cyst were not present; complete union and disappearance of the lesion is the rule. If operated on because of swelling or pain, the cavity is opened and swabbed with an antiseptic, such as alcohol, and the wound closed. Some surgeons fill the cavity with bone chips to promote osteogenesis. Lack of healing points to the existence of a systemic disturbance—such as Paget's disease of bone, generalized osteitis fibrosa, or bone lesions due to parathyroid tumor.

(*d*) *Benign Giant Cell Tumors.* This tumor occurs in many bones but is most common in the epiphysis of the lower femur, upper tibia, and distal radius. It produces pain, is often preceded by a history of trauma, and may be the site of fracture, thus resembling the symptoms produced by a bone cyst. X-ray reveals a central translucent trabeculated osteolytic lesion which has expanded and thinned out the cortex, perforating it often and invading soft tissue. *The fact that it involves the epiphysis is often of diagnostic value.* At operation, the tumor often appears hemorrhagic, bleeds when touched, and is soft and friable. Histologically, it contains many giant cells in contrast to malignant bone tumors which contain only a few such cells. Treat-

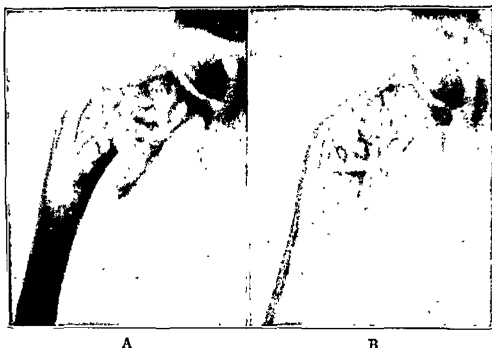

Fig. 30. Benign giant cell tumor. The existence of the lesion was discovered only by x-ray which was taken because the patient, aged four, had fallen and sustained a fracture. A, x-ray taken at time of injury; note the trabeculated nature of the shadow as well as the expansion of the cortex. B, x-ray taken three months later; the fracture was treated by reduction and immobilization in a plaster cast. This patient, now eight years old, is normal in every way.

ment includes radiotherapy, operation, or both.

Tumors containing giant cells comprise a variety of lesions (Fig. 30). Certain types of malignant bone tumors, though containing giant cells, have obviously an entirely different clinical significance. Giant cell tumors of the jaw, subperiosteal giant cell tumors, spindle cell variants, and types of giant cell variants in osteitis fibrosa present special features. Many giant cell tumors of bone are manifestations of hyperparathyroidism (see Ch. 39). The extraskeletal giant cell tumors include epulis, xanthoma, and giant cell tumor of the tendon sheath.

(*e*) *Multiple Cystic Disease.* This bone disease was described in 1891 by von Recklinghausen and is sometimes called Recklinghausen's disease; however, it has no connection with the more commonly known disease, neurofibromatosis, which he described in 1882 and which also goes by his name. The bone disease is often called osteitis fibrosa cystica or osteoplastica, but as originally described. Similar bone defects are observed in hyperparathyroidism as discussed in Chapter 38.

II. Nervous Tissue Origin. True neural tumors are rare except those in the brain (glioma), and as part of such other tumors as fibroneuroma (Fig. 31). Those which arise from the sympathetic nervous system are usually malignant and are called a variety of names, such as sympathicoblastoma and ganglioneuroma. *Carotid body tumors* belong to the chromaffin tissues which might be classed as of nervous origin. They are extremely rare and present themselves as a spontaneous, usually asymptomatic, swelling below and behind the angle of the jaw. Treatment is excision. (See also p. 652.) Spina bifida and meningocele are not really neoplasms and are described elsewhere. In the peripheral nerves, traumatic *neuroma* may result following injury or division of nerves. These are discussed in detail in Chapter 27. *Glomus tumors* are rare, tiny neoplasms which, however, contain vascular and epithelial as well as nerve tissue. They occur most frequently in the nail bed and about the

Cystology and Cellular Pathology of the Nervous System, Paul B. Hoeber.)

fingers and toes, elbow, knee, and leg. The tumors are characteristically painful, either spontaneously or to the touch, and therefore demand excision.

An easily recognized type of *neurofibromatosis* is *Recklinghausen's disease,* a rare but disfiguring affliction due to extensive multiple tumors of the skin (Fig. 32) and rarely of the deeper tissues. The tumors originate from the neurilemmal sheath of peripheral nerves and contain definite nerve filaments which, while diagnostic of the disease, are demonstrable only with special stains. Even though named after the German physician who reported the disease in 1882, a Dublin surgeon, Robert W. Smith, first described the condition in 1849 in a monograph which was privately printed and apparently lost to medical records. Fulton, in 1929, called attention to this communication. The eponymic term applied to the disease should possibly be that of Smith, whose description was accurate and included microscopic observations and carefully executed plates illustrating the lesion.

Fig. 32. Multiple neurofibromatosis. The patient was a 45-year-old Negress. No symptoms were present, except for moderate disability due to a tumor in the right axilla which was excised for that reason.

Clinical manifestations are generally due only to the appearance of tumors themselves. Pain, though generally absent, may be present in some cases. Because the tumors are often white, soft, and pedunculated, the term *fibroma molluscum* is also used. Areas of skin

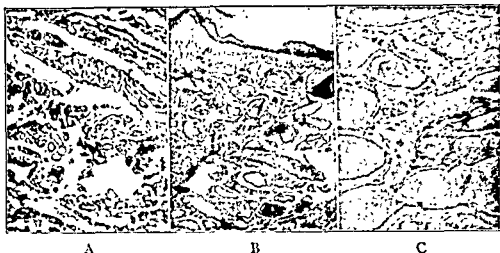

Fig. 33. The three types of blood vessel neoplasms described in the text. A, capillary hemangioma; photomicrograph is from a small port-wine stain excised from the neck of a two-month-old infant. Note the numerous small capillaries in the midst of many angioblasts; all of the channels contained blood. B, hypertrophic hemangioma; photomicrograph is from a small red tumor with roughened surface, removed from the arm of a six-year-old girl. Note the dilated thin-walled channels filled with blood. C, cavernous hemangioma; photomicrograph is from a tumor, about 3 cm. in diameter, over the elbow of a 12-year-old boy. A small tumor was present at birth but it began to grow markedly in the past three weeks. The skin may not be involved in this type of hemangioma. Note the thick-walled large sinuses filled with blood. This cavernous appearance is possessed by most of the hemangiomas encountered in the deeper structures of the body.

pigmentation are so frequently encountered as to be of diagnostic value. In addition to the skin lesions, which vary in size from that of a pea to that of a grapefruit, tumors are also found in the bone, central nervous system, and pelvis where they may cause severe symptoms of pain and disability merely by their pressure. Malignant (sarcomatous) changes are occasionally encountered and, unless the growth is removed early, recovery may be impossible. There is no treatment for the multiple skin tumors since they are usually too numerous for complete excision. When large and causing symptoms by pressure, removal may be urgently indicated. *Perineurial fibroblastoma* occurs in the same locations as Recklinghausen's disease but is usually single. Histologically it is differentiated from neurofibroma by the fact that the nerve fibers do not pass through the tumor nodule. They are common only along the eighth nerve (acoustic neuroma). Their treatment belongs to the domain of neurosurgery.

III. Blood Vessel Origin. Many of the various tumors arising from blood vessels are of neoplastic nature. Such lesions as aneurysms and arteriovenous fistulas are described in detail in Chapter 25. The blood vessel neoplasms are called angiomas or hemangiomas (Fig. 33) in contrast to lymphangiomas, which are somewhat similar in structure but contain lymph instead of blood. The angiomas are new growths, containing vascular tissue of capillary, venous, or arterial origin with a variable amount of connective tissue stroma. The vascular spaces are lined by endothelium and may be very large. Though congenital and present at birth, they sometimes have a power of growth which develops later or they may remain occult until adult life when symptoms may be produced. They occur in practically all tissues of the body and assume a great variety of clinical forms, to which many terms have been applied. Of those located in the deeper structures, most are of the cavernous type (see p. 413) and usually produce symptoms by pressure or by abnormal bleeding. They occur in the brain, orbit, intestines, pelvic organs, muscle, and especially in the liver and gastrointestinal mucosa, where they may be a rare cause of gastrointestinal hemorrhage. Symptoms depend on their location and size. True malignant change, including metastasis, has been described in angiomatous tumors, but it is extremely rare.

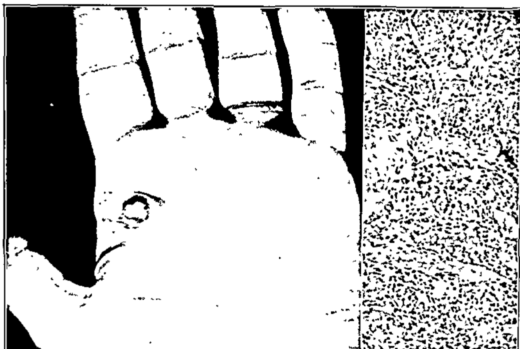

Fig. 34. Infected hemangioma of the hand. The patient was a 22-year-old housewife. This is a not uncommon type but the true diagnosis is often masked by the secondary inflammation which gives to the lesion the appearance of exuberant granulation tissue. This tumor was in the form of a papilloma and was easily excised. The photomicrograph reveals the true nature of the tumor; the dilated blood spaces resemble those shown in Figure 33B.

The visible hemangiomas, i.e., those which occur in or under the skin and mucous membranes, are perhaps the most common. In spite of the large and confusing terminology often applied to these lesions, the following classification has been adopted.

1. Capillary Hemangioma. The capillary hemangioma, or flat vascular nevus, is well known as the *port wine stain* and is sometimes called nevus flammeus or vinosus. Though a neoplasm, it is manifested not as a tumor at all, but as a disfiguring red or purple discoloration due to a plexus of newly formed, but normally sized capillaries in the corium of the skin. Its origin is probably due to some accident of maldevelopment during embryonic life, though popular superstition ascribes its etiology to some profound nervous shock to the mother while pregnant. Port wine stains ordinarily maintain a constant size and rarely increase in extent. The problem of treatment is a real one in the large areas which occur on the face or head. The use of radium has caused satisfactory blanching in some cases although it may be followed by a disfiguring scar. Skilled dermatologists sometimes achieve excellent results with carbon dioxide snow. Various tattooing devices have also been used. Excision and skin graft may occasionally be indicated.

2. Hypertrophic Hemangioma. The hypertrophic hemangioma, also called *angioma simplex* or angioma plexiforme, differs from the capillary nevus in being a true tumor, raised above the surface of the skin, though composed similarly of newly formed capillaries which, however, are dilated. The tumor varies in size from a millimeter to several centimeters in size; it shades gradually into the larger ones which are generally called cavernous angioma and have different histologic characteristics (see below). In color, the hypertrophic hemangioma varies from a bright red to a dull purple. The large, red tumor is often called a strawberry mark. Over 75 per cent of these tumors are on the head, commonly over the forehead, occiput, scalp, or lip, but may occur over any part of the body. The clinical course of this small angioma varies. A few seem to shrink and disappear. In some instances they ulcerate (Fig. 34), become infected, slough, and heal, leaving only a tiny scar. Most of them remain stationary or merely grow with the growth of

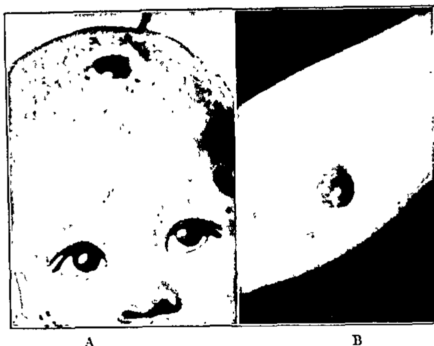

Fig. 35. Hypertrophic hemangiomas. A, the patient is a three-months-old infant; the tumor has been growing slowly since birth. Obliteration of the tumor was achieved by the use of radium. B, the patient is a five-year-old girl and the tumor of the leg has been growing slowly for several months. This tumor was excised. Section revealed a microscopic appearance approximately midway between that shown in B and C of Figure 33.

the child and are presented for treatment in childhood (Fig. 35) or adult life because they act as a cosmetic blemish. Of great importance, however, is the tendency of some of those tumors to exhibit rapid active growth, particularly in infants. If this occurs, a tiny birthmark of apparently no significance may finally involve an entire eyelid, nose, or lip, or spread over half the face or scalp, and finally become a true cavernous angioma. It must be emphasized, therefore, that every angioma in infants, regardless of its size, should be watched carefully and be removed even in the first weeks of life if any growth occurs. The treatment of the small lesions is relatively simple. Electrotherapy, irradiation of various types, and other means have been used, but should be carried out only by those expert in their use. Surgical excision is sometimes possible when the lesion is superficial.

3. Cavernous Hemangioma. This disfiguring vascular tumor usually involves a large part of the scalp, face, tongue, or other part of the superficial surfaces. Like the other vascular neoplasms, the tumor disappears on pressure but fills up rapidly. It differs from the other two types because of its size and because it contains true vascular channels (venous and arterial), which resemble the structure of the corpora cavernosa of the penis, hence its name. Cavernous hemangiomas present a grave problem in treatment, especially when they involve the face, for they are not only extensive superficially but often penetrate deeply and bleed profusely if any part of the mass is incised, thus making hemostasis during excision difficult. Because of the difficulties of surgical excision, other methods of treatment—such as diathermy, radiotherapy, and injection of various substances—have been tried from time to time and, in some instances, gratifying results have been achieved. The choice of method depends on the size and location of the tumor.

Other forms of congenital vascular tumors of the skin are described but are rather rare. *Angioma racemosum* or cirsoid aneurysm is composed of both arteries and veins which form large, serpentine swellings that pulsate visibly and give rise to an audible bruit due to the presence of many communications between the venous and arterial channels. They

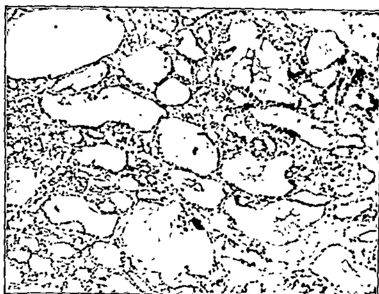

Fig. 36. Lymphangioma of the tongue. Photomicrograph of a tumor removed from the tongue (25-year-old woman. Note the dilated, thin-walled channels, which are, however, filled with lymph not red blood cells. Another differential feature is the frequent presence of nests of lymphocytes wl are seen only in lymphangiomas and not in hemangiomas. However, this tumor did not possess this ferentiating feature.

are in reality not neoplasms, but congenital abnormalities of blood vessels (arteriovenous fistula) and are described in some detail on page 569.

IV. Lymphatic Origin. Lymph channels are frequently involved by obstructive and inflammatory, but only rarely by neoplastic, disease.

1. LYMPHANGIOMA. This neoplasm of the lymphatic channels occurs in a great many clinical forms, usually, however, as a boggy tumor of the skin and subcutaneous tissue more particularly where the lymphatics are abundant (Fig. 36). It may occur in the form of a pedunculated mass. Lymphangioma may be a diffuse, slowly growing tumor involving the tongue or lip, giving rise to *macroglossia* or *macrolabia* (*microcheilia*), respectively. The tumor may be so disfiguring or result in such disability as to require excision and plastic repair. It should not be confused with *hemihypertrophy*, a rare congenital abnormality involving half the tongue, the lips, or even the entire head. Microscopic study reveals the difference. Lymphangioma often occurs concomitantly with cavernous hemangioma, which is occasionally associated with a type of varicose veins. Lymphangioma frequently contains islands of lymph cells in addition to lymphatic vessels. The channels themselves vary in size and, when large, p sent a cystic appearance (hygroma or ly phangiocysticum). When it occurs in neck (usually in infants), it is called *cy hygroma* and consists of multilocular lym filled sacs arising in the tissue beneath deep fascia. The large cystic mass (Fig. 3 frequently produces serious obstruction the trachea and esophagus and occasiona becomes infected, necessitating drainage. E cision is often difficult or impossible. Inj tions of sclerosing solutions are often usef Lymph nodes themselves do not give rise benign tumors of neoplastic origin except a part of lymphangioma. When enlargeme of lymph nodes occurs it is due either to i flammatory causes or to malignant diseas

2. THYMOMA. The term "thymoma" loosely applied to tumors originating from tl thymus gland. Actually there are vario types of growths, mostly malignant, whi cause symptoms by increased mediastin pressure. Thymic enlargement is physiolog in infants; when excessive, it is known *status thymolymphaticus*, a condition whic is also associated with general lympho hyperplasia and is supposed to be a cause sudden death in children.

V. Muscle Tissue Origin. Myoma of th uterus, often called fibromyoma because

Fig. 37. Cystic hygroma. In this child, aged 10 months, the lesion had grown since birth. Wide dissection is necessary for a cure.

contains fibrous as well as smooth muscle tissue, is common. It often grows to huge size and produces many local symptoms and signs (see Ch. 40). Leiomyoma, occasionally found in the stomach or intestine, is a cause of gastrointestinal hemorrhage. Though benign tumors of striated muscle (rhabdomyoma) also occur, they are so rare that they are recognized only after microscopic examination.

VI. Mixed Tissue Origin. There are two types of tumors in this classification: mixed tumors and teratomas.

1. MIXED TUMORS. This type occurs most frequently in and upon the salivary glands, most commonly the parotid (Fig. 38). Mi-

Fig. 38. Unusually large mixed tumor of the parotid. The patient was 47 years old. The tumor was first noted 18 years previously; after excision it recurred and grew more rapidly for four years when it was excised a second time. The present tumor is the second recurrence which has been growing slowly for 14 years. An extensive dissection was necessary before the tumor could be completely removed. The photomicrograph shows cords of epithelial cells which seem to form intercellular myxomatous material.

croscopic section reveals not only mesodermal cells, such as cartilage and fibrous tissue, but also epithelial elements and other tissue unrecognizable as to origin. There is usually a history of a small quiescent tumor for several years preceding active growth. When growth is rapid it is frequently indicative of malignant change. The typical tumor is firm, limited, and presents a nodular surface, later becoming cystic. These tumors recur unless completely and carefully removed together with their surrounding capsule. If not completely excised, an appreciable percentage of these tumors ultimately become malignant. Benign teratomas are also composed of mixed tissue, but are more obviously embryonic rests, and are described below.

2. TERATOMA. The teratoma represents, according to most authorities, an absorbed or partly grown twin which stopped development at some early stage and became encapsulated by the other normal fetus. Thus it contains, as already mentioned, mixed or diverse structures which are epithelial and mesodermal, e.g., muscle, hair, teeth, intestine, and the like. Great variations in size and development occur. A teratoma usually develops in the mid-line but is found most frequently in the testicle, ovary, sacrococcygeal region, and mediastinum. It causes symptoms by pressure, by undergoing malignant degeneration, or by both. It is, of course, present at birth, but often remains occult until symptoms develop later in life. It is described in detail in later chapters. When a teratoma contains skin elements only (hair and sebaceous material), it is often called a dermoid.

VII. Epithelial Cell Origin. The various benign tumors of epithelial origin are a rather heterogeneous group and, although a few are common, they represent in general rather rare types of benign tumors. They comprise three arbitrary groups: adenomas, skin tumors, and tumors of the jaw.

1. ADENOMA. This tumor is a benign collection of epithelial cells originating from glandular tissue. In endocrine glands, the tumor may actually function as secretory tissue, as noted in the hypoglycemia produced by adenoma of the islets of Langerhans of the pancreas (see Ch. 39). In the thyroid, adenomas may also cause symptoms but frequently occur "silently" without producing any manifestations of functional activity. In the pituitary, an adenoma may lead to abnormalities in growth; in the adrenal, it may produce peculiar sex development. Adenoma of the parathyroid may result in abnormal calcium metabolism and the formation of multiple bone lesions and renal calculi. When adenomas form in glands with external secretions, they rarely cause symptoms from functional activity since they rarely function as normal tissue. Thus an adenoma of the breast (usually fibroadenoma or intracanalicular fibromyxoma dependent on its microscopic features) does not produce milk but merely manifests itself as a circumscribed lump which is sometimes painful. Other circumscribed adenomas include the sebaceous adenoma which, though rare, may be the site of squamous or basal cell epithelioma. Treatment of adenoma consists of excision. *Rhinophyma* is a peculiar enlargement of the nose due to hypertrophy rather than to actual neoplasm of the sebaceous glands and skin. Plastic repair is often indicated.

Attention should be called to adenomatous hyperplasia which may result in papillomatous formation, especially in the stomach and colon (polyposis). Other examples of adenomatous hyperplasia are fungous or glandular endometriosis in the uterus, and prostatic hypertrophy.

2. EPITHELIAL BENIGN TUMORS OF THE SKIN. Prominent among the benign skin tumors are warts, cutaneous horn, and moles (or benign melanoma).

(*a*) *Warts* (*Verruca Vulgaris*). Warts are epithelial neoplasms originating from the germinative epithelium of the skin (Fig. 39). They sometimes are papillomatous, but usually are manifested as a cone-shaped elevation with a flat top whose surface exhibits a characteristic cauliflowerlike appearance and numerous tiny black dots. Warts have a tendency to become irritated, painful, and occasionally infected. Ordinarily, however, they produce no symptoms or, at the most, a slight "sticking" sensation. Nevertheless, when the warts are located under the nail, on the cuticle, or on the sole of the foot, pain may be pronounced. The tumor occasionally disappears spontaneously, sometimes within a short time after its development. This feature undoubtedly accounts for the reputed

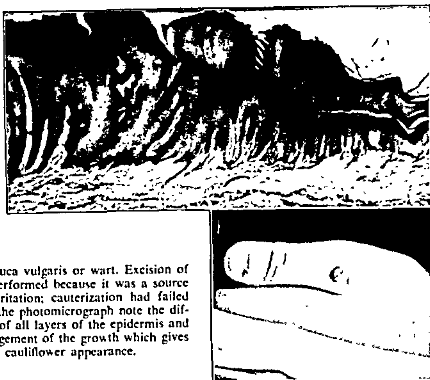

Fig. 39. Verruca vulgaris or wart. Excision of the tumor was performed because it was a source of mechanical irritation; cauterization had failed to destroy it. In the photomicrograph note the diffuse hyperplasia of all layers of the epidermis and the peglike arrangement of the growth which gives to the surface its cauliflower appearance.

efficacy of the many home remedies, some mixed with the use of magic formulas which have been used from time immemorial for their removal. The wart has considerable theoretical interest because, although possessing all the characteristics of a true neoplasm, evidence indicates that it is in reality an infection due to a filtrable virus. Thus, if the tumor is excised aseptically, ground up, and passed through a Berkefeld filter, the clear filtrate upon injection into the skin will give rise to a new wart. This probably explains why warts may appear and disappear suddenly without apparent reason, and why they may spread by contact as from one finger to a comparable point on the next digit or directly from a distal point to one proximal to it. It has been said that if we knew the pathogenesis of the common wart we would know something about the etiology of cancer.

Treatment is rarely indicated for cosmetic reasons because warts ordinarily grow on the hands and feet (Fig. 40). When infection is present it should be treated first. The tumor may be either destroyed or excised. Destruction of the wart may be achieved with 1. the x-ray; 2. by some form of cautery, e.g., electrical, thermal, or by chemicals (fuming nitric acid, trichloracetic acid, salicylic acid); or 3. surgical excision. Palmar and plantar warts are often the most difficult to eradicate. Irradiation is often effective in treating plantar warts but must be used with great care and only for one trial; if the lesion does not respond, surgical excision should be used. When the wart is more superficial and in soft, thin skin, chemical cauterization is the simplest method and consists simply of applying a drop of the acid over the plateau of the wart (not involving the adjacent skin) and letting it seep in. When it has reached the base of the growth a burning sensation is noted by the patient. The excess acid is then wiped off. The process may be repeated in 48 hours. After several days the wart drops out, leaving a shallow insignificant ulcer which heals readily. If a tiny recurrence occurs it can be treated similarly later.

(*b*) *Cutaneous Horn* (*Cornu Cutaneum*). The cutaneous horn is a form of cutaneous wart in which the horny layer (cornified epithelium) gives rise to the actual tumor. It may consist of a small area of hyperkeratosis, but fair-sized hard projecting growths may form, chiefly on the scalp.

(*c*) *Moles or Pigmented Nevi.* Moles occur commonly in the skin and are usually congenital. A much better term is *benign mela-*

Fig. 40. Plantar wart. The patient was a 16-year-old girl. Symptoms of pain and disability were marked. Note the slight redness, indicative of a mild degree of inflammation. Radiotherapy was curative in this case; it is obviously a very convenient form of therapy. Unfortunately it is not always effective.

noma. Clinically, benign melanomas are small raised areas which occasionally take the form of a papilloma and often have hairs growing out of them. Their importance lies largely in the fact that certain types give rise occasionally to the highly malignant melanoma (see p. 389). Excision is generally advisable if moles become chronically irritated or bleed, if sudden enlargement occurs, or if they are present on the feet. They may also be destroyed by the electrical cautery. Occasionally they are removed for cosmetic reasons when present in an exposed part of the body, particularly in young women.

3. JAW TUMORS. Though largely of ectodermal origin, jaw tumors comprise a great variety of neoplasms. They are varieties of odontomas or tumors derived from special cells concerned with the development of teeth. The following groups are described, modified from their classification:

(*a*) *Adamantinoma.* This neoplasm is a solid or often multilocular cystic tumor which develops within the alveolar bodies of the maxilla, but more frequently in the mandible. Microscopically it contains cells of squamous epithelium, or fibrous tissue, and even of the enamel organ. Clinically, it is slowly growing, is present most commonly in the molar region, and produces no pain. When large, it may present a lobulated surface and, upon pressure, the thin walls of the cyst may produce a sensation as of the crackling of parchment or celluloid. Excision is the only form of treatment, but must be complete in order to avoid recurrence.

(*b*) *Dentigerous Cyst* (*Odontocele, Corodental Cyst, Periosteal Cyst*). The dentigerous cyst is probably the most common tumor of the jaw and is a benign hollow cyst lined with epithelium containing viscid straw-colored fluid with a partly or fully developed tooth projecting into the cavity (Fig. 41). Symptoms arise only when they reach a sufficient size to be noticed. When large, the cyst may give a sensation of "celluloid crackling." Treatment consists of complete removal of the cyst and its capsule and extraction of the tooth. A *dental root cyst* is another type of jaw tumor and results from irritation of the dental epithelial cell rests in the peridental membrane of a tooth that has undergone eruption, usually a pulpless tooth.

(*c*) *Composite odontoma.* This is a calcified tooth tumor composed of varying elements which often demands excision.

Fig. 41. Dentigerous cyst. The patient was a 25-year-old male. This lesion produced no symptoms and was first noted in the roentgenogram which was taken because of an injury to the jaw. Note the fracture line extending into the cyst. (St. Louis City Hospital.)

(*d*) *Osseous tumors.* These tumors also occur in the jaw. In addition to the various types of benign bone tumors which may develop in the jaw, the so-called *fibrous osteoma* is a characteristic growth of the mandible.

All jaw tumors may become infected and the true nature of the tumor may thus be obscured. The roentgenogram is usually characteristic and enables an accurate diagnosis in most cases.

C. CYSTS

Cysts form a special group of tumors which owe their swelling to the presence of fluid rather than to cellular elements. However, the designation is far from absolute for many solid tumors contain cystic areas and many cysts harbor solid cellular areas. The clinical designation may also be difficult in that some sarcomas are soft and fluctuant as if they contained fluid, whereas some cysts contain fluid under such high tension that on palpation they resemble a hard, solid mass. Such difficulties, however, may usually be overcome by aspiration of the tumor. Cysts are much more difficult to classify than other tumors. The following groups, therefore, represent a purely arbitrary classification.

1. Retention Cysts. These tumors form because the duct of a gland becomes occluded, usually by inflammation, so that the secretion of the gland accumulates as a cyst.

Galactocele is a type of retention cyst in the breast which occurs during lactation and will be discussed in Chapter 35. *Mucoceles* are tiny cysts, commonly in the mouth, which are due to the occlusion of the opening of a tiny mucous gland. *Ranula* is a retention cyst located in the floor of the mouth under the tongue, is first confined to one side, later projects across the mid-line (Fig. 42). It is caused by an obstruction of one of the tiny, sublingual ducts which becomes distended with clear, mucoid material and often attains a large size.

The most common representative of the retention cyst is the so-called *wen* or *sebaceous cyst.* In its simplest form it manifests itself as the ordinary comedo in which the retained sebaceous material is visible under the skin. In its most pronounced form it presents a semispherical elevation in the skin to which it is attached. The tiny opening of the obstructed gland can often be seen at the apex of the tumor. It occurs most commonly in the scalp, back, and neck and may be multiple (Fig. 43). It is soft and fluctuant, containing characteristic greasy, thick, grayish paste. The contents sometimes escapes spontaneously or on pressure through a tiny opening, only to refill again. Complete excision of the sac is curative. Sometimes the cyst becomes infected, whereupon it presents the signs of an abscess which should be incised. The infection may destroy the secreting cells so that after inflammation subsides, recurrence may not occur. If it does fill up, excision can then be done. Malignant degeneration (carcinoma of a sebaceous gland) is rare but should be

Fig. 42. Ranula. The patient was a four-year-old boy. The smooth cystic tumor was *noted by the* mother accidentally. It increased in size steadily. Note that it is confined to one side of the floor of the mouth and does not cross the mid-line. Treatment consisted of complete excision of the cyst.

Fig. 43. Sebaceous cysts. Two of these tumors are present in this patient; they are of many years' duration and have been increasing *slowly in size. The one at the back of the head,* though unusually large, is in a characteristic location above the hairline; it was excised under local anesthesia and contained typical grayish greasy sebaceous material.

suspected if a draining sinus persists and fails to heal after incision of any superficial abscess of the skin or if a cyst develops sudden growth or unusual vascularity.

II. Degeneration Cysts. This term applies to cysts that sometimes form at the site of large hematomas which, instead of becoming absorbed and replaced with fibrous tissue, liquefy and remain as permanent tumors. They may be present in the abdomen after an intraperitoneal hemorrhage, in the chest, or in the brain. Ordinarily, the fluid is first brownish but later it undergoes changes which convert it into hematoidin (same as bilirubin), and colors the fluid yellow. Occasionally cholesterol crystals are found in such degeneration cysts.

III. Neoplastic Cysts. Neoplastic cysts generally include those which depend for their formation on a new growth, although in most cases the new cells are in reality abnormalities, congenital in origin. Ovarian cysts of various types have been described and belong in this group. Bone cysts have been described elsewhere under bone tumors.

IV. Dermoids or Dermoid Cysts. These terms should, in reality, include only cysts dependent for their formation on an inclusion of squamous epithelium under the skin. In some instances the cells continue to function as normal skin, and a cyst containing hair, sebaceous material, and cellular débris is formed. The small cysts, however, contain only clear fluid. The inclusion is usually congenital and occurs around the orbits, temple, mastoid and neck, or floor of the mouth. When a similar cyst is encountered in the ovary or mediastinum it should, in reality, be classified as a teratoma containing only epithelial elements. Dermoids of the skin, moreover, unlike ovarian and mediastinal dermoids, practically never undergo malignant change. Excision of the dermoids of the skin is indicated chiefly for cosmetic reasons. Those in the floor of the mouth are in the mid-line and may cause pressure symptoms; they are very rare, but should not be confused with ranula, which is unilateral. Those over the forehead should be distinguished from meningoceles which communicate with the brain; they may also be confused with lipomas and sebaceous cysts. Dermoids which occur in the sacral region are called pilonidal cysts or sinuses, and are seen frequently.

A *pilonidal cyst* is a derivative of skin ectoderm which becomes invaginated during embryonic life and remains only as a vestigial skin appendage, which develops at puberty (Fig. 44), thereby explaining its age distribution. Thus it rarely produces clinical manifestations until young adult life (20 to 25 years), and then only because the cyst becomes infected and forms an abscess which usually opens spontaneously and gives rise to a chronic draining sinus. This sinus may close, fill up, break down, and discharge intermittently. Occasionally the infection undermines the subcutaneous tissue over the coccyx and results in an extensive abscess. Even if drainage is adequate, healing will not occur, presumably because of the presence of living and therefore secreting epithelium in the lining of the tortuous sinus. During World War II, it assumed great importance because of its frequency and because it caused prolonged disability among the enlisted personnel. Many soldiers felt that riding on the hard seats of jeeps was a causative factor, which explains its popular name, "jeep disease."

Inspection in the sacral region will nearly always reveal one or more tiny dimples in the mid-line over the coccyx. They resemble in appearance the preauricular dimple seen in a branchial cyst at the first cleft (see p. 423). Such dimples are common and, on rare occasions, may be associated with severe local pain in absence of infection. Ordinarily, however, the superimposed infection contributes nearly all the local signs and symptoms. The location of the abscess or sinus opening over the coccyx plus the mid-line dimples are sufficiently characteristic to easily differentiate pilonidal infections from ischiorectal abscess and fistula in ano.

Treatment consists of complete excision of the diseased tissue after allowing acute infection to subside. All cells lining the tract must be removed, else recurrence is inevitable. This requires, in most cases, a rather extensive dissection; preliminary injection of the tract with methylene blue will aid in complete excision. Unless severe infection is present, the tract should be excised and the wound closed without drainage. However, in order to avoid a high incidence of infection and recurrence,

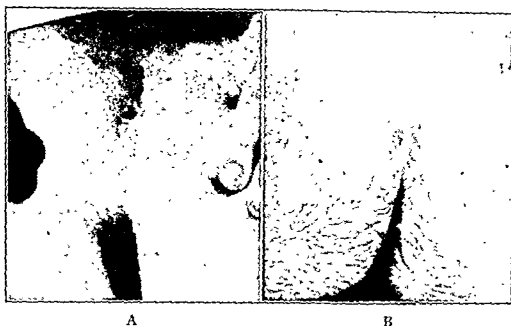

Fig. 44. Two examples of pilonidal sinus. A, in a 20-year-old girl; symptoms started at puberty with the appearance of a tender coccygeal mass which opened and drained pus only to heal and recur at intervals of many months. The photograph was taken a few days after the last abscess had opened and drained. Excision of the entire track was performed later after the acute inflammation had subsided. B, a more characteristic appearance in a 25-year-old male with a similar history. The acute infection has long since subsided and now exhibits only a tiny, chronically draining opening; the tract itself, however, extends upward and medially for several centimeters.

excellent surgical technic, including use of a minimal number of fine sutures, and elimination of all dead space must be exercised. When severe infection is present, the wound, after excision of the fistula, is packed open and allowed to close by granulation and fibroplasia.

Epidermoid cysts are similar in pathogenesis to dermoids except that they are due to traumatic inclusion of epithelial cells, often after a trivial wound, in which the cyst later develops. They are smaller than dermoid cysts, contain only clear fluid, and are common in the hands (fingers) and feet. Treatment consists of simple excision.

V. Congenital Cysts. This group includes several types:

1. Branchial Cleft Cysts. These cysts originate from the embryonic branchial clefts and hence occur in the lateral aspect of the head or neck along a line extending from the ear to the midclavicle (Fig. 45). The most common location is at the site of the first branchial cleft; a preauricular dimple is frequently seen and is often associated with a cyst just below and anterior to it. The cysts of the upper clefts are usually small, but those lower in the neck may attain considerable size. If they open or are incised they become the site of a chronic draining sinus. The cells lining the cyst in most instances are squamous in type, and the wall also shows many collections of lymphoid cells. Because of their similarity in structure, branchial cleft cysts are often classified with dermoids. Branchial cleft cysts which are deeper may communicate with the oral and pharyngeal cavity and exhibit columnar rather than squamous epithelium. Occasionally carcinomatous changes develop in them (Fig. 46). Their treatment consists of complete excision.

2. Thyroglossal Duct Cyst. This cyst is always in the mid-line of the neck and is a remnant of the thyroglossal duct which, in embryonic life, extends from the base of the tongue (foramen cecum) beneath the hyoid bone to form the thyroid gland (Fig. 47). Any portion of this tract may be left and give rise to a cyst in later life. It often opens spontaneously, after which it may manifest itself as a chronic draining sinus or as a cyst which opens, drains, closes, and fills up intermittently. Treatment consists of complete excision which may be difficult and may neces-

Fig. 45. Branchial cleft cysts at two different clefts. A, cyst of the first branchial cleft; note the preauricular dimple which is associated with the cyst but is often present alone; B, cyst of a lower cleft. Excision was performed in both cases; the lining of the cyst consisted of squamous epithelium and also contained nests of lymphoid cells.

Fig. 46. Carcinomatous change in branchial cleft cyst. The patient was a 70-year-old man. The tumor was of steady growth, apparently of only six months' duration. Aspiration of a cystic area yielded sufficient tissue to make a diagnosis of cancer. Complete excision was performed under local anesthesia.

sitate a dissection up to the base of the tongue. If any epithelial cells remain, recurrence follows. It is an operation which should not be undertaken lightly.

3. MENINGOCELE AND SPINA BIFIDA. These cysts are forms of congenital cysts due to failure in development of the central nervous system and its meninges and bony cover-

Fig. 47. Two examples of thyroglossal duct cysts. A, the cyst has not been opened. Note its position in the mid-line. It has been present for many years with very little increase in size; B, in this patient the cyst had been incised some years previously and the depressed scar is the site of a chronic draining sinus. The entire tract was excised; as is usually the case, an extensive dissection almost to the base of the tongue was necessary.

ing (Fig. 48). Spina bifida is most common over the lumbar region as a cystic mass and may be associated with motor and sensory disturbances. X-ray will reveal a bony defect, nearly always a bifid spine. Meningocele is really a herniation of the spinal or cerebral meninges through any bony defect which, however, is generally insignificant in size. It

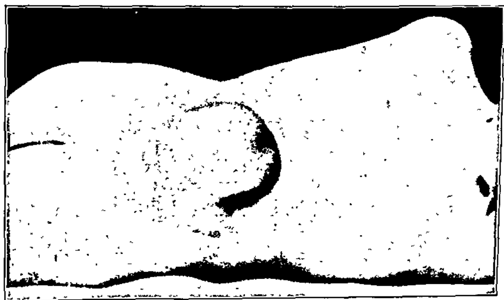

Fig. 48. Spina bifida and meningocele. The patient was a three-year-old girl. The mass was first noted at birth; the child had no use of either leg but was not incontinent. The defect in the spine could be felt clearly; transillumination showed a clear sac. Operative excision of the sac and plastic repair were performed; recovery was uneventful. Four years later the reflexes were still absent but the child was going to school, her grades being above normal. (Courtesy Dr. Ernest Sachs.)

is seen commonly in the lumbar region and less frequently in the mid-line over the forehead or occiput. *Treatment belongs to the* domain of neurosurgery.

4. POLYCYSTIC DISEASE. This rare form of congenital cyst, usually manifesting itself in adult life, occurs in the lungs, kidneys, liver, and spleen.

CANCER: RECENT CONCEPTS IN INCIDENCE, ETIOLOGY, DIAGNOSIS, DISSEMINATION, AND TREATMENT

INCIDENCE

Cancer ranks second, next to heart disease, as a cause of death in the United States. There are about 450,000 new cases per year and about 250,000 deaths, which represent about one sixth of the deaths annually. Contrary to popular belief, malignant disease is comparatively common in children. In 1956, 4,000 children under 15 years of age died of cancer, representing more deaths than from any other disease; only trauma accounts for more deaths in children. About half the deaths from malignant disease in children were caused by leukemia.

The number of deaths per year from cancer is increasing, not because treatment is less effective, or the incidence higher, but because cancer is a disease primarily of late adult life and people are living longer. In 1900, the life span was 48 years; whereas in 1957, it was an estimated 69 years. In spite of the increased incidence of cancer, the annual number of deaths for cancer in most sites of the body is leveling off because of improvements in therapy. However, the death rate from carcinoma of the lung is increasing sharply; for example in 1956, approximately 29,000 people died from carcinoma of the lung, which is fully six times the number 20 years ago.

The most common cancer in women is carcinoma of the breast; in men, carcinoma of the skin (1). The number of cases of and deaths from cancer in males and females have been assembled from vital statistics by Cameron (2) (Tables 1, 2).

ETIOLOGY

We must admit that the primary cause of cancer is unknown, although numerous secondary causes are known. These secondary agents might be classified as physical, chemical, or biological (3). Chronic irritation and inflammation represent secondary causes, but of more importance are the innumerable carcinogens which are known to be capable of producing cancer in animals. In surveying several hundred compounds, Hartwell (4) reports 320 as having carcinogenic qualities. There can be no doubt that this list is far from complete. We have only meager knowledge regarding the role of these agents in the production of cancer in the human being, although the hormonal influence (as will be discussed later) has been proved rather conclusively. It is very possible that certain of these factors, which we now classify as secondary, are actually primary factors. Only time and an enormous amount of research will give us the answer to this possibility. Certainly, some of the old theories, including Cohnheim's embryonal theory and the bacterial cause can perhaps be eliminated as having very slight or no etiologic importance.

TABLE 1. Estimated Cancer Incidence (1955) and Cancer Mortality (1953) in the United States Among Men

(After Cameron, in M. Clin. North America, May, 1956)

Site	Number	Total Per Cent of Cases in Men	Number of Deaths	Per Cent of Cancer Deaths in Men
Skin	31,000	13.6	2,095	1.8
Lung and bronchus	26,000	11.4	19,740	16 6
Stomach	24,000	10.5	14,752	12.4
Prostate	24,000	10.5	12,595	10.6
Large intestines	20,000	8.8	10,885	9.1
Buccal cavity and pharynx	15,500	6.8	3,995	3.4
Urinary organs	15,500	6.8	7,210	6.1
Rectum	13,500	5.9	6,087	5.1
Lymphomas	8,000	3.5	2,606	2.2
Leukemia and aleukemia	6,000	2.6	5,740	4.8
Pancreas	6,000	2.6	6,008	5.1
Esophagus	6,000	2.6	3,253	2.7
Larynx	6,000	2.6	1,800	1.5
Liver and biliary passages	5,000	2.6	4,377	3.7
Brain and nervous system	4,000	1.8	2,990	2.5
All other sites	17,500	7.7	14,694	12.4
Total	226,000	100%	118,827	100%

TABLE 2. Estimated Cancer Incidence (1955) and Cancer Mortality (1953) in the United States Among Women

(After Cameron, in M. Clin. North America, May, 1956)

Site	Number	Total Per Cent of Cases in Women	Number of Deaths	Per Cent of Cancer Deaths in Women
Breast	52,000	21.8	20,342	18.5
Cervix uteri	25,000	10.5	13,500	12.2
Skin	24,000	10.1	1,485	1.3
Large intestine	22,000	9.2	13,130	11.9
Stomach	12,500	5.3	8,621	7.8
Rectum	12,500	5.3	4,607	4.2
Ovary	11,500	4.8	6,483	5.8
Corpus uteri	8,000	3 4	2,000	1.8
Urinary organs	7,000	2 9	3,705	3.4
Lymphomas	6,000	2.5	1,762	1.6
Liver and biliary passages	6,000	2.5	5,470	5.0
Lung and bronchus	5,000	2.1	3,762	3.4
Leukemia and aleukemia	5,000	2.1	4,178	3.8
Pancreas	4,000	1.7	4,157	3.7
Buccal cavity and pharynx	4,000	1 7	1,084	0.9
Brain and nervous system	3,000	1.3	2,093	1.9
All other sites	30,500	12.9	13,873	12.6
Total	238,000	100%	110,252	100%

however, there is strong evidence (as discussed later) that a virus may be a factor, even of the primary type.

Some of the carcinogenic agents are foreign to the animal or human being (extrinsic); others are produced either by the animal itself or by other living organisms of different species (intrinsic). Accordingly, these agents will be discussed under these two headings.

There is another group of compounds

called cocarcinogens, which alone cannot initiate cancer but can promote cancer after a true carcinogen has been applied. These compounds are recognized in the pathogenesis of cancer in animals, but there is no proof that they exert a role in the production of human cancer. Creosote and croton oil are examples of cocarcinogens. For example, a single application of 3,4-benzpyrene to the skin of a mouse may not induce cancer; but if its application is followed by repeated treatment with croton oil, tumors will develop (Mottram, 1944). Croton oil itself will not produce cancer, and if applied prior to the application of the benzpyrene it has no effect.

Extrinsic Factors. Perhaps the first evidence we have of the recognition of a carcinogenic agent was the description of cancer of the scrotum in chimney sweeps by Sir Percival Pott in the eighteenth century. After development of the coal tar industry during the next century it was noted that workers in the tar distillation plants were prone to develop skin cancer. This occupational relationship was so obvious that many scientists were induced to apply tar to the skin of animals with the hope of producing a cancer. Most of their attempts failed because the local applications were not carried out long enough. The first production of cancer by local application of tar was reported by Yamagiwa and Ichikawa (5), who painted the ears of rabbits for 15 months.

POLYCYCLIC HYDROCARBONS. The production of cancer by application of tar soon led to the fractionation of coal tar into its different components, many of which are carcinogenic. This fractionation (from tar) or synthesis of such compounds as 1,2,5,6-dibenzanthracene, 3,4-benzpyrene, and methylcholanthrene (Fig. 1), furnished a new weapon in cancer research. The synthesis of the latter compound from desoxycholic acid and cholic acid, which are important components of the bile, suggests that elements in the bile might be carcinogenic particularly since desoxycholic acid has been shown to be carcinogenic (6). The polycyclic hydrocarbons produce tumors at the site of application, unlike most of the other carcinogens which produce tumors at distant sites.

HALOGENATED ALIPHATIC HYDROCARBONS. These agents are not nearly as important in carcinogenesis as the polycyclic hydrocarbons. However, it is known (Edwards) that feeding carbon tetrachloride in olive oil to mice for several months will produce neoplasms of the liver (hepatomas) in a high percentage of animals. However, feeding this compound in rats produces hepatic cirrhosis, but no tumors.

AZO DYES. Work on these agents was stimulated by the discovery (Fischer, 1906) that scarlet red would induce epithelial proliferation (which was not a true tumor). When amino-azotoluene is injected subcutaneously to rats and mice, a tumor of the liver is induced after months (Yoshida, 1934). This experiment was particularly important because it was perhaps the earliest one to demonstrate the production of tumors distant from the site of injection. When 4-dimethylamino-azobenzene is fed to rats for several months, a hepatoma is produced (Kinosita, 1937), but only in animals fed on a deficient diet (Rhoads and associates, 7). Many other azo dyes, including several derivatives of amino-azotoluene are carcinogenic.

AMINO COMPOUNDS. In this group are included such compounds as aminofluorene (with numerous derivatives), aminodiphenyl, aminostilbene, naphthylamine (alpha and beta), urethane, and the nitrogen mustards. The azo dyes are really amino compounds, but have been considered separately

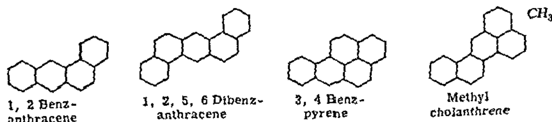

Fig. 1. Examples of extrinsic carcinogens (polycyclic hydrocarbons).

because they act so exclusively in the liver. The insecticide, 2-acetylaminofluorene, when incorporated in the diet of rats, will produce tumors in multiple areas (e.g., liver, bladder, breast) in three to four months (8).

FOODS. The possibility of certain foods being carcinogenic has been brought up by numerous workers, but no specific ones have been identified. The food itself could contain a carcinogenic agent or the harmful agent might be produced by the digestive process. It is conceivable that these agents might be carcinogenic to some people and not to others; this presumes that some people are blessed with the possession of anticarcinogens, which is discussed later.

TRAUMA. At times, there appears to be a relationship between trauma and the development of malignant tumors, but with very few exceptions this relationship is not valid; on most occasions it was some trauma, slight or otherwise, which called attention of the patient to a nodule or a beginning pain. On the other hand, chronic irritation can be an etiologic factor. One of the best examples of this is the transformation of a nevus from a benign lesion to a melanotic sarcoma when located at the belt line or at a place where clothing may be a source of chronic irritation. This is different from the occasional production of squamous carcinoma of the lip by the irritation of a pipe stem, because the melanotic sarcoma required the presence of a certain type of nevus.

Intrinsic Factors. These factors result primarily from metabolism within the body and may be normal or abnormal states. The two important intrinsic factors are hormones and viruses (3), of which the latter may, on certain occasions, be extrinsic in origin.

HORMONES. Perhaps the first suggestion of relationship of hormones to production of cancer was the demonstration that the incidence of mammary cancer was higher in animals prevented from breeding than in breeding females of the same stock (Lathrop and Loeb, 1916). Lacassagne (9) was the first to induce mammary cancer in animals by injection of hormones; he did so by injecting a mixture of estrone, equilin, and equilenin (from the urine of a pregnant mare) into castrated male mice. However, there is no positive evidence that the administration of female sex hormones to women will induce cancer, although cancer of the male breast has been reported in men undergoing heavy stilbestrol therapy for carcinoma of the prostate (10). Sex hormones act in a synergistic way in producing experimental cancer, as shown by the demonstration of Strong (11), that neither estrone nor methylcholanthrene alone will induce mammary cancer in male mice of the C_3H and $C_{57}BL$ strain, but cancer is induced if the two agents are given simultaneously. When diethylstilbestrol is fed to male mice of the susceptible C_3H strain of mice, mammary tumors develop within 20 weeks after the initial administration (Shimkin and Grady, 12). Estrogen, when fed over a long period of time, may also induce the formation of testicular tumors. The experiments of Biskind and associates (13) constitute a good example of the carcinogenic effect of hormonal imbalance; they induced tumors in ovaries transplanted into the spleen of castrated rats. This may indicate that the liver possesses the ability to inactivate ovarian hormones or that the increased formation of pituitary gonadotrophin subsequent to castration is a potent causative factor. Kirkman and Bacon (14) report production of bilateral renal tumors in male hamsters after prolonged therapy with large quantities of diethylstilbestrol. Likewise, cancer of the bladder is produced in rats (associated with urinary calculi) if diethylstilbestrol pellets are planted subcutaneously (Dunning and associates, 15).

The above data indicate that there is a strong relationship between sex hormones and development of cancer in animals, but the evidence of such a relationship in the human being is much less pronounced. There is ample evidence that deprivation of male and sex hormones in human beings with advanced cancer exerts a favorable influence on regression of the tumor. This will be discussed later in this chapter and also in Chapter 35. Additional data may be found in the Symposium on Endocrinology of Neoplastic Diseases (16), by numerous authors.

Rats treated with pituitary growth hormone over long periods of time develop neo-

plasms of the lungs, lymphatic tissue, adrenals, and reproductive organs (17).

VIRUSES. The first demonstration that a virus may cause cancer was that of transmission of the chicken sarcoma by injection of cell-free extract of a tumor to another chicken (Rous, 1911). Leukosis can also be transmitted in fowls by cell-free plasma with the production of sarcomas as well as endotheliomas and myeloleukosis (Stubbs and Furth, 1935). In 1933, Shope demonstrated that the spontaneous papillomas of rabbits could be transmitted from one rabbit to another by injecting a cell-free extract of the tumor. Additional evidence of the virus theory, at least in animals is the work of Bittner (18) (1936), who showed that when offspring of a high tumor strain of mice were suckled by foster mothers of a low breast-tumor strain, the foster nursed mice showed a low tumor rate. These experiments indicated that the mothers of the high tumor strain transferred the tumor or, more accurately, its etiologic factor to her progeny; this agent must accordingly be a virus. It is found in all tissues of the body, is destroyed by heating at 65° F. for 30 minutes, and is filterable through a Berkefeld or Seitz filter.

Numerous workers have suggested that the etiologic cause of human cancer is a virus, but up-to-date proof is lacking. Stanley (19) has been a strong proponent of the virus etiology in the human being. Critics of the virus theory argue that, if a virus was the cause of human cancer, there would be more evidence of contagion and someone would surely have demonstrated it by this time. Stanley counters with the fact that many viruses are difficult to isolate. Furthermore, he calls to our attention the knowledge that the psittacosis virus can exist in a group of parrots and certain other birds for long periods of time without manifestations, but under crowded conditions the disease may suddenly break out with virulence. Also, certain potato viruses can be passed from generation to generation without causing apparent disease. Stanley states further that "We know that viruses can persist in their host for generations, in either an infectious or noninfectious form. We know that viruses may mutate to form new strains that cause different symptoms. We know that different carcinogenic agents can activate subinfections or latent viruses or prophages with consequent cellular destruction." Accordingly, Stanley contends that the persistence of a virus in man for years or generations without manifestations should not be regarded as unexpected or unusual. For these reasons, he insists that there is good evidence to indicate that the primary cause of cancer is a virus.

It is believed that certain carcinogenic agents are produced in the body by normal or abnormal metabolism. For example, there is good evidence that methylcholanthrene may arise from bile acids through abnormal metabolic processes.

Environmental Causes. Many of the environmental causes of cancer are extrinsic in type and some, including tar products such as encountered by chimney sweeps and workers in the coal tar industry, have therefore been discussed. However, these factors are discussed separately because they are such obvious and such important causes of cancer. Many of the agents identified as environmental causes represent industrial hazards.

OCCUPATIONAL CANCERS. There are numerous occupational cancers in addition to the tar cancers and chimney sweep cancers, both of which involve the skin. Workers in certain textile plants developed cancer of the scrotum, produced by the constant spray of mineral oil over them. Much of the evidence just mentioned was accumulated in Britain. In Basel, A. Mueller (1933) reports that in dye factories the incidence of bladder cancer was 33 times as frequent as in the normal population. This is the so-called "aniline cancer" presumed to be induced by the aromatic amines. In this type of cancer, β-naphthylamine has been incriminated by Hueper (20); it will produce bladder tumors in dogs. Asbestos, and certain metals, including chromates and nickel, will produce cancer of the lung (20).

Hueper has called attention to the fact that the latent periods of some of the tumors mentioned in the preceding paragraph vary from 1 to 50 years. The average for the tar cancers was 22 years; for the mineral oil cancers it was 50 to 54 years; for the carcinomas of the lung produced by asbestos, chromates, and

nickel it was 18, 15, and 22 years respectively. Other details of occupational cancer may be found in publications by Greenstein (3) and Vorwald (21).

RADIATION. This factor has long been known to be a cause of cancer. There are numerous types, but the simplest is sunlight; this relationship has been known for years. It has been shown (Findley, 1928) that the inciting factor in sunlight is most likely ultraviolet radiation, since experimental cancer can be produced by the latter factor.

There is much evidence to indicate that *radioactive substances* can produce cancer. For example, cancer of the lung has been described in the workers in mines of the Joachimsthal and Schneeberg mountains, which at present are being worked for uranium ore (22). For centuries, the death rate from cancer of the lungs has been so high there that it has been estimated that 90 per cent of all cancers in these miners originates in the lungs (23). It has been known for decades that osteogenic sarcoma is common in radium dial painters (Martland, 1931). It is also known that plutonium (Pu), strontium (Sr^{90}), and phosphorus (P^{32}) will produce bone tumors and occasionally lymphomas in mice.

Radiation from radioactive material will also produce leukemia. For example, in the survivors at Hiroshima and Nagasaki the incidence of leukemia in survivors 2,000 or more meters from the point of explosion was three times the control rate, but for people 1,000 meters or less from the point of explosion it was 20 times the control rate (22).

It is well known that frequent *exposure to x-ray* is apt to produce a carcinoma. The most common examples of this are found in physicians who use fluoroscopic x-ray examination without proper protection of the hands. Many physicians have lost part of the hand or had to have resection of the skin of the dorsum of the hand, with skin graft, to eliminate squamous carcinoma, which is much more apt to develop following numerous exposures of small doses than after one or two massive doses of x-ray therapy. A minimum of five years is required for this transformation to take place. Cancer will also develop in the ulcer induced by an x-ray burn. In such cases there is no assurance that the x-ray exposure was the cause of the cancer since similar neoplasms (i.e., squamous cell carcinoma) will develop, within 10 to 30 years, in a neglected ulcer produced by a thermal burn (Fig. 2). Leukemia may also be induced by exposure to x-ray therapy; it

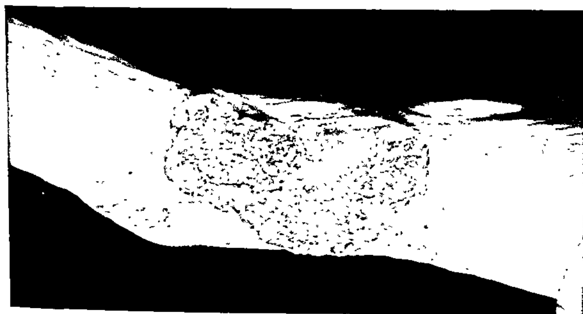

Fig. 2. Squamous carcinoma in a burn of the arm. The patient had a third-degree burn 20 years ago. The granulating area had never completely healed. One year ago the ulcer began to enlarge and the edges became hyperplastic. Biopsy was positive.

is 1.7 times more common in physicians than lay individuals (Henshaw, 1944). The above data may worry us additionally lest exposure to x-ray without a burn result in an increased incidence of cancer. Actually, Spitz and Higginbotham (24) have reported osteogenic sarcomas in patients given large doses of x-rays. However, the incidence is not high enough to contraindicate the use of x-ray therapy.

CIGARETTE SMOKING. Of all the carcinogenic factors, cigarette smoking is receiving the most attention at the present time. During the past several years numerous investigators, in different countries, have studied the relationship between cigarette smoking and cancer of the lung. Practically all of them have arrived at the same conclusion; namely, that cigarette smoking increases the chance of developing lung carcinoma, particularly in men. Wynder and Graham (25) were among the first to report. In Britain, Doll and Hill (26) arrived at the same conclusion. Tar obtained by condensation of the cigarette smoke will produce cancer when painted on the skin of mice (27, 28). In Wynder and Graham's experiments, the cancer did not develop until 71 weeks (half the mouse life span) had elapsed since start of the painting. Chemical analysis of the smoke yields 3,4-benzpyrene (29, 30). There has been considerable argument as to whether the carcinogenic agents are in the tobacco or in the cigarette paper, particularly since chemical analysis reveals 3,4-benzpyrene in the smoke of cigarette paper as well as of the tobacco (30). However, there is no agreement that there is enough benzpyrene in the condensate of cigarette smoke to produce the cancer in the animal experiments.

In the analysis of a study carried out by the American Cancer Society on 190,000 men over a 44-month period, Hammond and Horn (31) report that, in men, cigarette smoking increases the death rate from numerous causes, particularly cancer of the lung.

The death rate from cancer of the lung in men who smoked half a pack of cigarettes per day was 7.3 times as great as in nonsmokers; the rates for men smoking half to one pack, one to two packs, and two or more packs per day were 8.4 times, 18.0 times, and 21.0 times greater respectively than the rate for nonsmokers. Surely this sharp increase in deaths from cancer of the lung in the men smoking cigarettes, with an increasing mortality as the smoking increases, would convince anyone that cigarette smoking increases the probability of contracting cancer of the lung. The death rate in cigar smokers was about the same as in nonsmokers; in pipe smokers it was about 3 times as high as in nonsmokers. The above figures exclude adenocarcinoma of the lung, the incidence of which is presumably not related to smoking.

The death rate from cancer of the kidney was 1.58 times higher in cigarette smokers than in nonsmokers, from cancer of the prostate it was 1.75 times higher, and from cancer of the bladder 2.17 times higher than in nonsmokers. The death rate from cancer of the colon and rectum was the same in smokers as it was in nonsmokers, but slightly higher from cancer of the pancreas (1.5 times) and stomach (1.6 times). However, the death rate from liver and gallbladder cancer was 4.5 times higher in cigarette smokers than in nonsmokers.

Of considerable interest, but unrelated to the subject of this chapter, was the fact that the death rate from coronary disease was 2.41 times greater in men smoking two or more packs of cigarettes per day than it was in nonsmokers. In the groups smoking less, the death rate decreased in a manner parallel to the decrease in smoking.

In general, the death rate from cancer of the lung of men in large cities was greater than in men living in rural areas, when groups with equal smoking habits were compared. This could probably be explained on the basis that noxious gases and smoke from automobiles, industrial plants, and so forth, may also be factors in increasing the incidence of cancer of the lung. In fact, Kotin (32) reports that painting the skin of animals with foreign material obtained from the atmosphere of a large industrial city produced cancer. From his study of the American Cancer Society data, Hammond (33) estimates that 31 per cent of the deaths from cancer of the lung were due to air pollution. From studies

in Liverpool, Stocks and Campbell (34) estimated that about 35 per cent of the deaths from cancer of the lung resulted from air pollution, a figure remarkably close to Hammond's estimate.

MISCELLANEOUS FACTORS. There are numerous other environmental causes not related to occupation, e.g., radiation or smoking, which we shall identify only as environmental. *Smegma* appears to be an important carcinogen insofar as carcinoma of the penis is extremely rare in circumcised men, and carcinoma of the cervix is rare in groups which practice circumcision. Moreover, cervical cancer has been produced in mice by the local application of smegma. Recently, it has been shown that heavy consumption of *whisky* is an important factor in the development of carcinoma of the larynx (35) and possibly of the esophagus. Under such circumstances, it may act as a cocarcinogen. *Schistosomiasis* is an important factor in the production of bladder cancer. In Egypt (36), there is less evidence that the Schistosoma parasite is a causative factor of cancer of the liver. Data from India (37) indicates that betel nut chewing increases the incidence of cancer of the oral cavity and hypopharynx. However, it is not clear whether or not betel nut alone will produce cancer, since tobacco is usually an ingredient of the quid.

MECHANISMS AND AVENUES OF CANCER RESEARCH

Before the end of the last century research in cancer was very limited and unscientific. This was due in part to the fact that no promising mechanisms were available, there were no animal tumors to use, and significant experiments on the human being were obviously not feasible. Since the beginning of the present century numerous mechanisms for performing research have been developed. The amount of experimentation and publications have accumulated in such volume that no one person can possibly keep up with the data. This has given rise to the writing of numerous books and monographs which help greatly in supplying information to each worker in his field. Cancer research has attracted brilliant scientists, of whom many have made great contributions. However, as Greenstein (3) says "for some odd reason cancer research has been the graveyard of many a scientific reputation." Nevertheless, cancer will continue to present a challenge and entice good experimentalists, largely because the stakes are high and the reward great —professionally, not financially—for fine contributions. All of us know that the person who discovers the cure or true cause of cancer will probably receive an acclaim unequaled in the annals of medical history. Many vital discoveries have been made in cancer research, but we are still so short of the final goal that we must assume a still greater accumulation of knowledge will be required.

The first great step in the development of a mechanism for research was the successful transplantation of a tumor by Hanau from one rat (wild) to another at the end of the last century. The later development of a good experimental animal—the albino rat—by Chicago scientists (Slye, Wistar, and associates) was another very important advancement. The discovery of the x-ray and radium emanation at the turn of the century supplied us with a good therapeutic tool. A few years later, various strains of mice were developed which had certain characteristics regarding susceptibility and immunity to certain tumors. L. C. Strong and C. C. Little have been important pioneers in this field. Special credit should be extended the latter for his influence in developing the laboratory at Bar Harbor, Maine, which supplies scientists with animals of various strains. As stated previously, the first successful production of an animal tumor (by painting tar on the ears of rabbits for 15 months) by the Japanese scientists Yamagiwa and Ichikawa (5) represents a very important milestone.

Progress made in the past several years indicates that the chemical treatment of cancer, including hormones and antibodies, may offer hope of being very effective. One of the first examples of this mechanism was Coley's toxin (1893), which was effective on only an occasional case, primarily sarcoma. The first effective use of hormones was reported by Huggins and associates (37), although it had been known for decades that castration was often effectual in causing regression of carci-

Cancer research has attracted brilliant scientists, of whom many have made great contributions. However, as Greenstein (3) says "for some odd reason cancer research has been the graveyard of many a scientific reputation." Nevertheless, cancer will continue to present a challenge and entice good experimentalists, largely because the stakes are high and the reward great —professionally, not financially—for fine contributions. All of us know that the person who discovers the cure or true cause of cancer will probably receive an acclaim unequaled in the annals of medical history. Many vital discoveries have been made in cancer research, but we are still so short of the final goal that we must assume a still greater accumulation of knowledge will be required.

The first great step in the development of a mechanism for research was the successful transplantation of a tumor by Hanau from one rat (wild) to another at the end of the last century. The later development of a good experimental animal—the albino rat—by Chicago scientists (Slye, Wistar, and associates) was another very important advancement. The discovery of the x-ray and radium emanation at the turn of the century supplied us with a good therapeutic tool. A few years later, various strains of mice were developed which had certain characteristics regarding susceptibility and immunity to certain tumors. L. C. Strong and C. C. Little have been important pioneers in this field. Special credit should be extended the latter for his influence in developing the laboratory at Bar Harbor, Maine, which supplies scientists with animals of various strains. As stated previously, the first successful production of an animal tumor (by painting tar on the ears of rabbits for 15 months) by the Japanese scientists Yamagiwa and Ichikawa (5) represents a very important milestone.

Progress made in the past several years indicates that the chemical treatment of cancer, including hormones and antibodies, may offer hope of being very effective. One of the first examples of this mechanism was Coley's toxin (1893), which was effective on only an occasional case, primarily sarcoma. The first effective use of hormones was reported by Huggins and associates (37), although it had been known for decades that castration was often effectual in causing regression of carci-

noma of the prostate and ovary. In 1946, Goodman, Gilman, and associates (38) reported the beneficial use of nitrogen mustard in human cancer.

It is well known that the effects of various types of cancers on animals, and the effects of various anticancer agents on the cancers of animals, cannot be transferred literally to cancer in man. The growth of human tumors in animals would allow experimentation, with results which would be much more applicable to human cancer. Under ordinary circumstances human tumors will not grow in animals. However, in 1952, Greene (39) reported that human tumors could be grown in the anterior chamber of the guinea pig eye. He reported that the tumor grew in 65 cases and failed in 58; however, not all workers have been able to obtain a growth in such a high percentage of cases. The discovery by Toolan (40) that treatment of animals with cortisone or x-irradiation will condition animals so that human tumors will grow when transplanted subcutaneously (e.g., into the pouch tissue of a hamster) offers a better mechanism of studying the effects of various agents on tumors which, at least, were derived from the human being.

SYSTEMIC EFFECT OF CANCER ON THE HUMAN BODY

Surprisingly few alterations are produced by cancer in the body (except in late cancer) other than those which can be explained on the basis of changes induced by pathologic processes itself; e.g., loss of plasma and blood from an ulcerating tumor. Numerous workers have discussed the possibility of a cancer "toxin," but as yet there is no evidence that one exists. However, Graham and Graham (40a) have presented evidence that antibodies exist. Of 48 cancer patients tested for antibodies to their own tumor by complement fixation technic, 12 had a titer of 1:16 to 1:28. The majority of patients not showing antibodies had far advanced cancer.

Loss of weight is a fairly constant symptom. On most occasions it is caused by lack of intake of food; this lack of intake may be caused by anorexia itself or to pain. Loss of weight is pronounced in patients with oral cancer, due primarily to difficulty or pain with swallowing. Loss of plasma and blood from an ulcerating tumor may also produce weight loss. In carcinoma of the stomach weight loss is often the first symptom; invariably in such early cases, lack of intake due to anorexia or postprandial distress is the cause.

Hypoproteinemia is a fairly common manifestation of cancer. Usually it is due to loss of plasma and blood from an ulcerating tumor. In the later stages of the disease, when metastases are growing to considerable size, it can be explained by the transfer of nitrogen from normal body tissue to cancerous tissue, a natural process which is almost bound to exist at this stage because intake is usually insufficient to furnish adequate nitrogen to both tissues. On other occasions, the hypoproteinemia appears to be caused by liver dysfunction, since the synthesis of plasma protein is carried on primarily by the liver.

Liver dysfunction has been noted by Abels and associates (41) in a high percentage of patients with gastrointestinal cancer. Their studies include data on plasma prothrombin, serum protein, vitamin A, urinary excretion of glucuronates, and metabolism of urobilinogen, serum cholesterol, and serum cholesterol esters. During the second stage of tumor growth the liver enlarges, although in the ante-mortem stage of the disease there is a decrease in liver weight (42). The lipids in the liver increase.

There are changes in the level of many *enzymes*, primarily a decrease. One of the enzymes most constantly lowered in almost all types of animals with experimental cancer is liver catalase. It has been studied by numerous workers; the data accumulated by these scientists have been summarized by Greenstein (3). Other enzymes, including hepatic and renal d-amino acid oxidase, and esterase, are also lowered. Reduction of the latter may be due to hepatic insufficiency because it is synthesized by the liver, the functions of which often are impaired by cancer. The presence of inhibitors of the trypsin enzymes—including trypsin, chymotrypsin, plasmin, and rennin—in the serum is well established, insofar as relatively small quantities of serum will inhibit the enzymes (43).

In fact, there are inhibitors of numerous other substances; details may be found in the splendid monograph by Greenstein (3).

In certain tumors (e.g., Walker 256 carcinosarcoma rat tumor) the *adrenals enlarge* to a degree equal to about twice the usual weight (44). The exact significance of this phenomenon is unknown.

Anemia is a fairly common manifestation in patients with cancer. On most occasions this can be explained readily by bleeding from an ulcerated cancerous surface. On other occasions it appears to be caused by hepatic insufficiency and/or bone metastases. The anemia may be of various types and often, indeed, not readily explainable. The various types and possible mechanisms are ably discussed by Ley (45).

Hypercalcemia is a fairly common manifestation, most often seen in advanced cancers which have invaded the bone. The calcium may enter the vascular system from the bones, by the gastrointestinal tract, or by the parenteral route. Various aspects of this condition are discussed by Myers (46).

In certain types of cancer, isolated changes are encountered which are primarily specific for that tumor. The *elevation of the acid phosphatase level* in the blood of patients with carcinoma of the prostate is an example of this phenomenon. However, with few exceptions, this elevation is encountered only in disseminated cancer—not in nondisseminated cancer (Gutman, 1938). An elevated level may reveal the presence of metastases before the x-ray can reveal gross changes. However, the elevation of acid phosphatase in the salivary excretion of the parotid gland, as noted by Hoerman and associates (47), may be a much more sensitive test and appears to be of great diagnostic value. The test was positive in 80 per cent of patients with carcinoma of the prostate. In 20 per cent of patients there was a false negative, and in 10 per cent a false positive test.

PSYCHOLOGIC EFFECTS OF CANCER

The public is aware of the serious consequences of cancer, and the contraction of the disease is accordingly associated with a variable amount of emotional shock. However, a great deal of the shock sustained by the cancer patient is related to ignorance. A surprisingly large percentage of patients consider cancer a hopeless disease, not realizing that if the lesion is treated early the chance of a cure is quite good, providing the proper treatment (primarily, operation or radiation) is carried out. Another fear experienced by many patients is the supposition that, even if the cancer is treated successfully, a serious disability may result from the treatment; most of these are, of course, unfounded. Still another fear possessed very often by the patient, as well as by his family, is that the disease is contagious and will be transmitted to other members of the family. The contagious element is entirely unfounded; only very seldom does there appear to be a slight hereditary trait.

Since a major portion of the worry created by the patient's fear that he may have cancer is related to lack of information about diagnosis, methods of therapy, prognosis, and so forth, it would appear that a campaign of lay education would be desirable. Numerous agencies are aware of this, and one of them particularly, the American Cancer Society (with its numerous divisions), conducts a continuous campaign to educate lay people as well as doctors. These mechanisms of education for lay people are carried out in numerous ways, including lectures, pamphlets, movies, and television shows. One of the most effective single factors is a movie entitled, "Self Examination of the Breast for Women." Invariably, when this movie is shown to an audience of a few hundred women, several of the audience report to physicians' offices during the next few days with breast tumors, a few of which are malignant; these cancers are invariably early ones in which prognosis is very good with prompt proper treatment. A few physicians claim that such a campaign will instill so much fear in the minds of lay people that it will do more harm than good. The author is convinced this is not so, believing that fear of cancer created in this way can be allayed very quickly by a thorough negative examination by a physician, followed by a sincere assuring talk about the problem. If the patient still has cancer phobia after a negative examination and an assuring talk with his or her physician, it is the author's opinion that a phobia of some

noma of the prostate and ovary. In 1946, Goodman, Gilman, and associates (38) reported the beneficial use of nitrogen mustard in human cancer.

The contagious element is entirely unfounded; only very seldom does there appear to be a slight hereditary trait.

Since a major portion of the worry created by the patient's fear that he may have cancer is related to lack of information about diagnosis, methods of therapy, prognosis, and so forth, it would appear that a campaign of lay education would be desirable. Numerous agencies are aware of this, and one of them particularly, the American Cancer Society (with its numerous divisions), conducts a continuous campaign to educate lay people as well as doctors. These mechanisms of education for lay people are carried out in numerous ways, including lectures, pamphlets, movies, and television shows. One of the most effective single factors is a movie entitled, "Self Examination of the Breast for Women." Invariably, when this movie is shown to an audience of a few hundred women, several of the audience report to physicians' offices during the next few days with breast tumors, a few of which are malignant; these cancers are invariably early ones in which prognosis is very good with prompt proper treatment. A few physicians claim that such a campaign will instill so much fear in the minds of lay people that it will do more harm than good. The author is convinced this is not so, believing that fear of cancer created in this way can be allayed very quickly by a thorough negative examination by a physician, followed by a sincere assuring talk about the problem. If the patient still has cancer phobia after a negative examination and an assuring talk with his or her physician, it is the author's opinion that a phobia of some

other kind would develop if cancer phobia were obliterated. In a questionnaire survey conducted by Samp and Curreri (48) it was noted that only 3.5 per cent of 560 patients interviewed stated that the educational campaign conducted by the American Cancer Society and other agencies was "too much." Many of the individuals interviewed thought the campaign initially made them fear cancer, but 97 per cent of those replying to that question thought the explanation offered by the educational campaign lessened the fear. After all, we must instill a certain degree of fear in the minds of people to get them to go to a physician. Too often indeed, when we ask the patient with an inoperable or incurable cancer why he or she waited so long the answer is, "Well, it was giving me no pain, and I did not think it was serious." We must continually emphasize that lack of pain in a tumor nodule does not eliminate cancer.

One of the most important points in the consideration of cancer and the patient is the question as to whether or not the patient should be told he has a cancer. There has been considerable argument on this point. In the author's opinion the question cannot be answered "Yes" or "No." There can be no question that certain patients sustain no emotional imbalance whatsoever upon hearing the news, along with proper information, whereas other patients collapse to the point of a psychiatric complication. Accordingly, in the author's opinion, the physician must know his patient, telling those who can tolerate the news and not telling those who might be seriously disturbed emotionally by the knowledge that they have cancer. Unfortunately, one cannot assume that the patient who requests he be told has sufficient emotional stability to withstand the news; in fact, the patient who insists loudly and strongly that he be told is often the one who will collapse the most completely when he is told. One can withhold the exact information from the patient with very few exceptions by explaining that he has a tumor. When asked if this is cancer, the honest reply can be that it is a type of cancer, but one in which you expect good results if that is the case. If you cannot truthfully expect good results, the patient and family invariably receive great comfort from the statement that "we" should be hopeful, because occasionally such tumors, though appearing very serious, sometimes grow very slowly and, in fact, now and then disappear entirely. There is good evidence that this is true (49). In any event, some responsible member of the family must be told the exact diagnosis and expected prognosis, even though the physician chooses to withhold the correct diagnosis from the patient. If the patient is to have a permanent colostomy, he must be told this before operation and the entire situation explained to him, assuring him that at first there may be considerable emotional disturbance from the colostomy, but that with practically no exceptions the patient adjusts completely to it. Often, it will be necessary for the patient to talk to someone with a permanent colostomy before he will sign an operative permit.

It must also be emphasized that the physician must not neglect the terminal cancer patient simply because he cannot cure him. Often, proper psychologic aid afforded by the physician's attention and time will be sufficient to make life tolerable for the patient and his family. Too often, indeed, the physician neglects the patient with terminal cancer. He needs your help and you must not ignore him. Likewise, as the patient's physician you should encourage him to seek comfort in religion; sometimes this must be done very cautiously and skillfully lest the patient think you are deliberately preparing him for the great beyond. Serious emotional imbalance in patients who are very unstable has been discussed by Sutherland (50).

MECHANISMS OF SPREAD OF CANCER

The physician cannot treat a tumor intelligently unless he is familiar with the usual methods of spread. It must be emphasized that no two tumors behave exactly alike, even though they have the same appearance and are of the same type. Accordingly, we must treat each tumor as an individual problem, even though we realize the methods of spread will vary. In general, there are four major methods of spread (but not all tumors spread by all four mechanisms): 1. by lymphatics; 2. by local implantation; 3. by contiguity through tissue planes; and 4. by venous emboli.

Lymphatic Metastases. The classical work done by the British surgeon, W. Sampson Handley, many decades ago, was very helpful to the surgeon in planning the operative removal of malignant tumors and served to stimulate additional work which has been carried on by numerous investigators (51). Certain types of tumors spread by lymphatics more actively than others; the cells travel in the lymphatic channels to lymph nodes. When a lymph node becomes blocked with tumor cells, there is a tendency for additional cells to travel onward to more distant nodes through collaterals. In addition, cells will travel from one node to another, usually in the direction of lymph flow, rarely against it. If surgical incision extends beyond all of the tumor and involved nodes, a cure can be expected *unless venous metastases have already taken place*. It must be remembered that microscopic metastases may be present in lymph nodes beyond the extent of excision and may not be palpable.

Extension by Contiguity. Practically all malignant tumors spread by this mechanism, some faster than others. Obviously, practically any tissue may be invaded, depending upon the location of the tumor. The tumors which invade most extensively by contiguity through tissue planes, with formation of bulky tumors, are not necessarily the most dangerous, and vice versa. Often large bulky tumors are curable, and small, seemingly local ones may metastasize (via veins) extensively. Accordingly, tumors which have spread extensively by contiguity should, in general, be operated on unless their excision involves removal of vital tissue necessary to life.

Local Implantation. One of the best examples of implantation of malignant cells is a *recurrence developing in a wound* a few weeks or months after excision of a malignant tumor. If the tumor was inadequately excised, the recurrence may, of course, represent a continued growth from the original tumor. This type of recurrence may not be preventable, simply because the tumor was inoperable. We are much more concerned about the recurrence in the wound after an operation during which the tumor was widely removed with no obvious primary or secondary tumor remaining (Figs. 3, 4). These are theoretically preventable and result from too much manipulation of the tumor or from cutting across a vein or lymphatic which happened to contain some viable cancer cells. In the latter case, irrigation of the wound with the proper chemical may remove the vast majority of these cells. Actually, cancer cells can be found in the wound washings at the completion of an operation. In a study of 120 patients having radical operation for cancer, Hilberg and associates (52) found cancer cells in the wound washings in 26 per cent and doubtful cells in an additional 14 per cent. Very significant in their study is the fact that in 30 per cent of cases in which all gross tumor was removed the wound washings were positive.

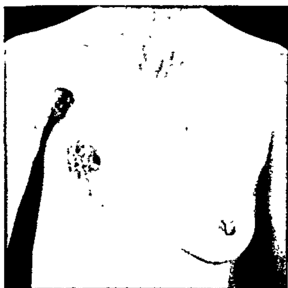

Fig. 3. Recurrent carcinoma, most likely resulting from implantation. The patient had a radical mastectomy five years ago for an adenocarcinoma of the breast. Six months ago she noted a small nodule growing in the scar of the incision made then. It was removed widely and a skin graft applied. (After Cole et al. Bull. N.Y. Acad. Med.)

A few years ago, three different groups (53, 54, 55) independently became alarmed over the high incidence of *local recurrence at the suture line* following resection of the colon for carcinoma. All three groups concluded that implantation was the most logical explanation for most of the recurrences, and recommended procedures, as discussed later, to prevent or minimize that complication. The best explanation for this type of implantation is contamination of the suture

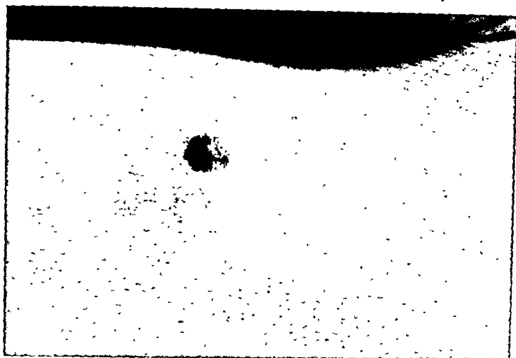

Fig. 4. Recurrent melanoma in the scar of a biopsy. Four months previously a subcutaneous nodule of the arm was removed for biopsy. Microscopic examination revealed a metastasis from a melanoma originating elsewhere.

line with loose cells from the operative field and their transplantation into the wall as the anastomosis is being performed. At least, there is fairly good evidence that the recurrence is secondary to implantation on some occasions. For example, in a series of 11 patients with recurrence at the suture line following resection of the colon, Fleischner and Berenberg (56) found a silk suture in the recurrent tumor in three cases; this phenomenon has been reported by others (57).

Innumerable types of implantation have been reported; they have been discussed by Ackerman and Wheat (57) and Cole and associates (58).

Venous Spread. For many years, pathologists have called attention to the invasion of veins within the tumor—especially of the rectum and colon—but clinicians have not attached the proper importance to this finding. For example, lymph node metastases are serious; so is the local growth of the tumor, by contiguity; but the *lethal factor is the venous invasion*. Accordingly, it deserves intense study.

Grinnell (59) found invasion of veins, microscopically, within the tumor in 36 per cent of patients with carcinoma of the rectum and in 33 per cent of patients with carcinoma of the colon; Brown and Warren (60) report it in 61 per cent of patients with carcinoma of the rectum. The study by the latter authors was made in autopsy specimen, thereby accounting for the higher incidence.

In 1954, Cole and associates (61) reported the demonstration of malignant cells in blood from the vein, obtained by perfusion, draining from the tumor (rectum). Fisher and Turnbull (62) later studied more cases and found cancer cells in the venous blood draining from the tumor (colon and rectum) in 31.4 per cent of cases. Turnbull (63) reports further that the incidence of positive cells in the venous blood was 28 per cent when performing colectomy with the usual technic, whereas they were present in only 13 per cent of cases when the colectomy was performed without handling the tumor. This supports the theory that handling a tumor breaks off loose cells, which act as emboli and lodge in the lungs or liver or circulate throughout the body. Engell (64) has made an extensive search for malignant cells in the venous blood and reports finding them in blood draining from the tumor in 54 per cent of 76 patients with cancer of the rectum,

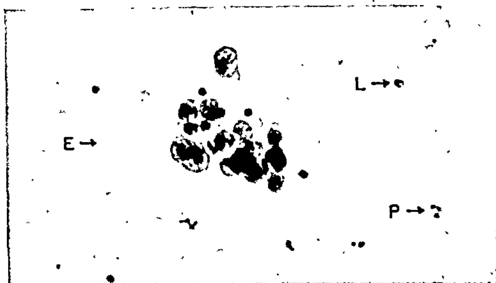

Fig. 5. Malignant cells isolated from the peripheral blood of a patient with an advanced carcinoma of the breast. Compare the clump of malignant cells with L, the lymphocytes, P, the polynuclear leukocytes, and E, the erythrocytes.

and in 70 per cent of 31 patients with cancer of the colon. In his series, cells were found in 0 per cent of patients with Grade I tumors, in 35 per cent of patients with Grade II tumors, in 78 per cent of patients with Grade III tumors, and in 100 per cent of patients with Grade IV tumors. He reports finding cancer cells in the systemic blood in 13 per cent of 79 patients with operable cancer, and in 50 per cent of 14 patients with inoperable tumors. With reasonable care, these cells can be identified and differentiated quite accurately from normal blood cells (Fig. 5), as shown by Roberts and associates and others (65, 66).

DIAGNOSTIC METHODS

The routine methods in history taking and physical examination are discussed in detail in Chapter 2. Moreover, various diagnostic methods have been described with the surgical lesions as they have been presented. Accordingly, a complete description of methods here would be superfluous. However, there are certain features which are peculiar to cancer; these will be emphasized. Fortunately, the majority of cancers are visible or palpable by digital examination, including vaginal and rectal examination. However, many of those not palpable are extremely difficult to diagnose.

History. There are very few points in the history which are diagnostic of cancer as a disease itself. Often, indeed, a history of loss of weight and weakness is encountered in many types of cancer (e.g., stomach), but diabetes, tuberculosis, and many other diseases will produce the same symptoms. Pain is so commonly absent in early cancer that it is of little help diagnostically except in a reverse manner; e.g., early cancer of the breast rarely produces pain, whereas chronic cystic mastitis with few positive findings may produce considerable pain.

Abnormal bleeding from any orifice is often, indeed, due to cancer. This is particularly true of rectal bleeding if the fresh bleeding of hemorrhoids is excluded. Occult blood may be just as helpful as gross bleeding, particularly if it is present constantly and the patient is on a meat-free diet.

The history of a brain tumor may be quite diagnostic. For example, if a patient complains of headache and disturbances in the visual fields, one must consider the presence of brain tumor until proven otherwise.

Inspection. The lesions visible by inspection alone are primarily the epitheliomas of the skin and mucous membranes of the oral cavity. Cancer of the cervix and rectum is diagnosable by digital examination; with the aid of the vaginal speculum and proctoscope they can be visualized. Most epitheliomas of the skin will be ulcerated. Malignant nodules

line with loose cells from the operative field and their transplantation into the wall as the anastomosis is being performed. At least, there is fairly good evidence that the recurrence is secondary to implantation on some occasions. For example, in a series of 11 patients with recurrence at the suture line following resection of the colon, Fleischner and Berenberg (56) found a silk suture in the recurrent tumor in three cases; this phenomenon has been reported by others (57).

Innumerable types of implantation have been reported; they have been discussed by Ackerman and Wheat (57) and Cole and associates (58).

Venous Spread. For many years, pathologists have called attention to the invasion of veins within the tumor—especially of the rectum and colon—but clinicians have not attached the proper importance to this finding. For example, lymph node metastases are serious; so is the local growth of the tumor, by contiguity; but the *lethal factor is the venous invasion.* Accordingly, it deserves intense study.

Grinnell (59) found invasion of veins, microscopically, within the tumor in 36 per cent of patients with carcinoma of the rectum and in 33 per cent of patients with carcinoma of the colon; Brown and Warren (60) report it in 61 per cent of patients with carcinoma of the rectum. The study by the latter authors was made in autopsy specimen, thereby accounting for the higher incidence.

In 1954, Cole and associates (61) reported the demonstration of malignant cells in blood from the vein, obtained by perfusion, draining from the tumor (rectum). Fisher and Turnbull (62) later studied more cases and found cancer cells in the venous blood draining from the tumor (colon and rectum) in 31.4 per cent of cases. Turnbull (63) reports further that the incidence of positive cells in the venous blood was 28 per cent when performing colectomy with the usual technic, whereas they were present in only 13 per cent of cases when the colectomy was performed without handling the tumor. This supports the theory that handling a tumor breaks off loose cells, which act as emboli and lodge in the lungs or liver or circulate throughout the body. Engell (64) has made an extensive search for malignant cells in the venous blood and reports finding them in blood draining from the tumor in 54 per cent of 76 patients with cancer of the rectum,

Fig. 6. Early carcinoma of the stomach (pylorus). This lesion was so small it was demonstrable only by taking an oblique view. Symptoms consisted of dyspepsia of three months' duration.

colon), the surgeon does not need to rely upon a biopsy. However, an indurated lesion in the sigmoid associated with diverticula might be a cancer or diverticulitis. Under such circumstances, he may resect the lesion and wait for a diagnosis from the pathologist before he proceeds with a radical resection. On other occasions (e.g., cancer of the middle or upper third of the esophagus), few surgeons indeed will proceed with the usual cancer operation before biopsy confirmation because the mortality of such operations is high and he does not wish to submit the patient with a benign lesion to such a high mortality rate.

It is readily understandable that the surgeon would like to have a positive diagnosis in every patient with cancer before he proceeds with the operation. However, he is confronted with the question as to how often biopsy will disseminate the cancer. It appears that, in ulcerating lesions of the rectum, a biopsy which is taken from the mucosal surface should not induce any dissemination. Unquestionably, venous dissemination is much more dangerous than lymphatic, since the former travels far beyond the limits of the resection. Accordingly, biopsy in epitheliomas, which rarely metastasizes by vein, will be quite safe.

However, in tumors which are vascular and notoriously metastasize by vein (e.g., tumors of the breast, thyroid, and pancreas), biopsy may not be innocuous. Already we are learning that a needle biopsy may be dangerous. Ackerman and Wheat (57) have reported many instances in which the tumor grew out alongside the needle tract. Davis (67), studying patients in the Illinois Research Hospital clinic, found that the five-year survival rate in patients with cancer of the breast who had aspiration or incisional biopsy 1 to 20 days before radical resection was much lower than that for the entire group. The five-year survival rate for those having excisional biopsy was about the same as for

in the subcutaneous tissue beneath the skin are apt to be metastatic, commonly melanotic sarcomas, the pigment of which can often be seen through the skin. Lesions of the oral cavity will be visible by using a flashlight and tongue blade, but those in the hypopharynx and larynx will usually require the use of laryngoscopic mirrors. Many tumors reveal themselves as abnormalities in shape and conformity of various parts of the body, e.g., sarcoma of the bone.

The ulcerations of cancer, regardless of the type of lesion, are fairly characteristic. This is true of cancers of the skin, the mucous membranes of the oral cavity, and the gastrointestinal tract. The surface is seldom smooth, being either granular or with a cauliflowerlike nodularity. The ulcerations bleed readily. The less nodular portions of the granulating surface usually have a granular appearance; these granules are either gray or grayish yellow in color.

Palpation. Palpation may reveal a nodule or nodules which may be benign or malignant. Most malignant ones are hard, but not stony hard. Most primary lesions will have an irregular surface. On the other hand, metastases to lymph nodes may have a fairly smooth surface. Very few malignant lesions are acutely tender. Superficial nodules can sometimes be diagnosed correctly as malignant nodules, usually of the metastatic type. Lipomas are lobulated and softer than malignant nodules. Lymphomatous nodules are usually quite soft and, at times, so vascular and cellular that they appear fluctuant. Fixation of the mass is usually indicative of malignancy, although inflammation can produce this immobility.

X-Ray Examination. The x-ray is extremely helpful in the diagnosis of malignant disease, and, in fact, the clinician could not get along without it. On innumerable occasions, the x-ray is the deciding factor.

Plain x-ray films may reveal destructive lesions in the bone or cancer of the lung. A shadow of a malignant tumor on a plain film may be seen, but the shadow alone gives us no lead as to whether it is benign or malignant.

Fluoroscopic examination is often able to make a positive diagnosis, whereas without it differentiation would be very difficult. Cancers of the hepatic flexure, splenic flexure, and certain parts of the stomach often would not be diagnosable without the fluoroscope (utilizing barium as a contrast media).

The use of *barium as a contrast* media is extremely helpful in diagnosis. In fact, the x-ray has perhaps reached its peak of diagnostic accuracy in cancer of the gastrointestinal tract. In the stomach, the x-ray is very accurate (Fig. 6) except in the malignant ulcers which often cannot be identified even with the naked eye. For the colon, the barium enema is a very accurate diagnostic mechanism, except that in cancer of the rectosigmoid area the lesion is often hard to demonstrate.

Delineation of the *kidney outline with opaque media* is extremely valuable in diagnosing renal tumors. As described in Chapter 41, this may be achieved by intravenous or retrograde urography. The x-ray is not of much aid in diagnosing *cancer of the gallbladder* primarily because the gallbladder is usually badly diseased, casting no shadow with oral cholecystography (or even intravenous cholecystography, cholegrafin). Stones are usually present with cancer of the gallbladder, but the vast majority of stones are not associated with cancer. The important characteristics of *sinuses* and *fistulas*, including particularly their connections, can be well identified by the injection of such opaque substances as diodrast and hippuran into them. However, the outline of the sinus or fistula in itself will rarely be helpful in determining which is associated with cancer.

Laboratory Tests. X-ray examination, as described above, may be classified as a laboratory test and is extremely helpful. Numerous laboratory tests, as described in Chapter 3, will be helpful in diagnosing the secondary effects of cancer (e.g., hypoproteinemia and occult blood in the stool) but to date there is no specific test for cancer.

Biopsy. Microscopic examination of tissue is perhaps the most accurate mechanism of all in the diagnosis of cancer. True enough, the percentage of accuracy is dependent upon the skill of the pathologist. However, even a good pathologist is helpless without an adequate biopsy taken from the proper area of the lesion.

For certain lesions (e.g., carcinoma of the

tron, with x-ray beam and electron beam; 4. linear accelerator; 5. synchroton; and 6. isotopes. Details of the type of ray and the application of the various machines or agents have been discussed by Laughlin (69).

Experience has taught us that radiation is fairly effective against certain tumors and not others. For example, x-ray, commonly with 250,000 electron volts capacity, is very effective in cancer of the lip and often is used as the sole method of treatment in such cancers. It is also quite effective in numerous types of lymphomas (especially Hodgkin's disease), cancer of the cervix, and many others. In general, x-ray therapy is much less effective against metastases than against the primary. It is practically ineffective against all cancers of the gastrointestinal tract. The betatron, which develops 20,000,000 or more electron volts, has greater penetrating power without skin reaction. It accordingly is useful in treating deep lesions such as carcinoma of the esophagus. The linear accelerator, which develops at present up to 50,000,000 electron volts, and the synchroton, which develops even more (70,000,000 electron volts), may have still greater advantages, but clinical experience with them is still limited.

Numerous isotopes—including I^{131} (iodine), P^{32} (phosphorus), Au^{198} (gold), Co^{60} (cobalt), Ta^{182} (tantalum), Ir^{192} (iridium), and Br^{82} (bromine)—are being used, but experience with the last four is quite meager. I^{131} is used primarily for cancer of the thyroid, but less than half of the carcinomas of the cancerous thyroids will pick up the iodine even when stimulated with TSH (thyroid stimulating hormone). Au^{198} is being used in the treatment of cancer of the prostate and is also used in the peritoneal cavity at the end of an operation to "kill" tiny implants or displaced cells. P^{32} has been used in the treatment of leukemia, carcinoma of the breast, and certain other tumors.

Prophylactic or Adjuvant Therapy. Operative technic has developed to a degree approaching its maximum efficiency, yet a large number of patients having operations of the curative type develop recurrence in spite of surgery. Accordingly, we must seek other mechanisms of improving results. One of the obstacles in obtaining good results is the failure to have the patient report to the physician before his condition becomes inoperable or hopeless. A continual educational campaign must be maintained to improve this situation.

It is very important that when patients with palpable cancers are examined, the mass should be examined very gently, and by as few individuals as possible. Rough handling of the tumor unquestionably gives rise to lymphatic and particularly to venous dissemination. A common error made in clinical practice in the operating room is the use of soap and water preparation in patients with a palpable malignant tumor, particularly cancer of the breast. During the skin preparation preliminary to operation, no method of preparing the skin should be used which allows rubbing the skin over the tumor. This could be very damaging by producing venous emboli.

Of more importance, perhaps, than the precautions in technics listed above would be the destruction of the disseminated cells. It occurred to Cole and associates (70, 71) that these cells might be destroyed by some of the anticancer agents now in use, although they will not kill cells which are entrenched in a metastasis having an established blood supply. This group of workers designed an experiment utilizing Walker 256 carcinosarcoma cells. They inoculated the cells into a branch of the portal vein of rats to stimulate venous emboli to the liver in a human being, and then gave 0.5 mg. per kilogram of nitrogen mustard into the same vein one minute later. The same dosage was carried out in another series of rats, giving the nitrogen mustard into the peritoneal cavity one hour after inoculation; and in another, giving the nitrogen mustard into a systemic vein one hour after inoculation of the cells. These investigators found that, when nitrogen mustard was given at the time of the inoculation or within an hour afterwards, the nitrogen mustard was quite effective in decreasing the percentage of "takes"; for example, "takes" were reduced from 91.7 per cent in controls to 17.8 per cent in the treated animals when the nitrogen mustard was given one minute later into the same vein. When nitrogen mustard was given into the peritoneal cavity one hour after inoculation of cells, the percentage of "takes" in the controls was 86.7 per cent and in the treated animals was 41.3 per cent. Thio–

the entire group. All surgeons will agree that if a biopsy of the breast or thyroid is performed, the resection of the cancer should be carried out immediately after the frozen section report of cancer, if at all possible. The 95 cases reported by Davis as having operation 24 or more hours after biopsy had their biopsy in hospitals elsewhere and were sent to Illinois Research Hospital for operative care. Also, all surgeons agree that when a biopsy is performed, gloves, instruments, and drapes must be changed before the resection is begun, lest the surgeon implant cells into the massive wound created during the resection.

PRINCIPLES IN TREATMENT

In spite of an enormous amount of work being done on numerous methods of therapy, surgical excision and radiation remain the only curative procedures for cancer. Many agents are palliative, some prolong life and others do not.

Surgical Resection. Gradual progress has been made during the past few decades in the operative treatment of malignant disease. The development of refinements in anesthesia and the proper use of blood have made radical operation for cancer possible with a comparatively low mortality rate. The extent of operation has been increased but cannot be increased much more because of anatomic limitations. Super radical procedures—such as excision of the rectum, bladder, prostate, or uterus at one stage—are being performed for advanced tumors, but the five-year survival rate from these procedures is low whereas the mortality rate is high. The surgical profession is at present evaluating the benefits, operation mortality, disability, and so forth, trying to arrive at standards which would clarify the indications and contraindications of these massive operations for advanced cancer.

It must be emphasized that operations for cancer are distinctly different from operations for benign lesions. The primary difference lies in the fact that in cancer operations the surgeon must remove all tissue, if possible, which may possibly harbor cancer cells. Accordingly, he must be trained in the finer technics of surgery, allowing him to perform massive operations without damaging vital structures and without jeopardizing the patient's life from the standpoint of the patient's physical reserve.

The majority of patients with cancer have one or more serious decrements in physical reserve by the time they come to the surgeon for operation. One of the most common and most important is malnutrition, which is very frequent in oral and gastrointestinal cancer because of inadequate intake resulting from pain (when eating, in oral cancer) and digestive disturbances (in gastrointestinal cancer).

For reasons enumerated above, meticulous preoperative preparation must be carried out in many patients with cancer. Preoperative examination should routinely include blood protein and N.P.N. determinations, in addition to routine blood and urine examinations. There are two primary motives for these precautions: 1. to obtain indications for treatment and improvement of operability; and 2. to plan the operation in case certain decrements cannot be corrected. One of the most common errors made today by capable surgeons is to proceed with a conventional type of operation when the patient's physical reserve will not actually tolerate it. In other words, we must not perform a given operation on a patient if we have good reason to think he will not survive it. True enough, the patient often dies when we thought he would survive. This is not an excuse for our error but should serve to stimulate us to assay our patients operability more closely; we hope the day will come when we can say with certainty that a certain patient will survive a certain operation and not another. We must be prepared to alter the type and extent of our operation (perhaps in stages) if it will save the patient's life.

Radiation. There are numerous types of radiation, most of which induce changes in the nucleus of the cell which interfere with mitosis. Primary radiations used clinically include x-rays, gamma rays, electrons, beta rays, neutrons, and protons (68). The secondary radiations projected into the tissues consist of protons and electrons. Of the numerous machines or agents being utilized in the treatment of cancer the following should be mentioned: 1. x-ray; 2. radium; 3. beta-

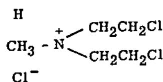
TABLE 3. Specific Agents Used in Cancer Chemotherapy

(Modified from Karnofsky in CA—Bulletin of Cancer Progress, 5:170, 1955)

Agents	Principal Route of Administration	Usual Dose	Acute Toxic Signs	Major Late Toxic Manifestations
		Polyfunctional Alkylating Agents		
Methyl-bis(β-chloroethyl)amine HCl (HN_2) (Mustargen)	I.V.	0.4 mg./Kg. single or divided doses	N.&V.*	Therapeutic doses moderately depress peripheral bloodcell count; excessive doses cause severe bone-marrow depression with leukopenia, thrombocytopenia, and bleeding. Maximum toxicity may occur two or three *weeks after last dose. Dosage,* therefore, must be carefully controlled.
Triethylenemelamine (TEM)	I.V. Oral	0.04 mg./Kg ×3 20–40 mg. in 1 mo.	Occasional N.&V.*	
Triethylenethiophosphoramide (Thio-TEPA)	Oral I.V.	5–10 mg./day 0.2 mg./Kg ×5	None	
1,4-Dimethanesulfonyloxybutane (GT-41) (Myleran)	Oral	2–8 mg./day 150–250 mg./course	None	
		Antimetabolites		
4-Amino-N[10] methylpteroylglutamic acid (Amethopterin)	Oral	2.5–5.0 mg./day	None	Oral and digestive-tract ulcerations; bone-marrow depression with leukopenia, thrombocytopenia, and bleeding.
4-Aminopteroylglutamic acid (Aminopterin)	Oral	0.25–1.0 mg./day	None	
6-Mercaptopurine (6-MP) (Purinethol)	Oral	2.5 mg./Kg./day	None	Therapeutic doses usually well tolerated; excessive doses cause bone-marrow depression.
		Steroid Hormones and Related Substances		
Androgen				
Testosterone propionate	I.M.	50–100 mg. 3× weekly	None	Fluid retention, masculinization.
Methyltestosterone	Oral	100 mg. daily	None	Fluid retention, masculinization.
Estrogen				
Diethylstilbestrol	Oral	1–5 mg. 3×daily	Occasional N.&V.*	Fluid retention, feminization, uterine bleeding.
Ethinyl estradiol	Oral	0.1–1.0 mg. 3× daily		
Adrenal Cortical Hormones				
Cortisone acetate	Oral	50–300 mg. daily	None	
Hydrocortisone acetate	Oral	50–200 mg. daily	None	Fluid retention, hypertension, diabetes, increased susceptibility to infection.
Meticorten	Oral	20–100 mg. daily	None	

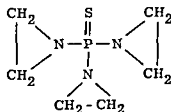
TEPA has the same, and perhaps more, effect than nitrogen mustard when used in this prophylactic or adjuvant way. As soon as it was discovered that the nitrogen mustard was effective in a prophylactic way in animals, Cole and associates began (March, 1956) its use in human beings. As yet, it is too early to draw any conclusions from the procedure.

Chemotherapy. For many decades, efforts have been made to treat cancer with anticancer agents, but the early agents were not very effective. Perhaps the first one which offered promise was Coley's bacterial toxin, initiated about 1893. A few very beneficial effects were observed, but in the majority of cases no benefit was noted.



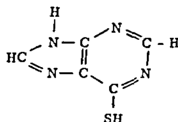
Nitrogen mustard, the first promising chemical agent introduced, was found by Goodman, Gilman, and associates (38) to be effective experimentally as well as clinically, although no clinical cures could be obtained. Nitrogen mustard produces its effect by substituting alkyl groups for hydrogen. The most likely site for this substitution process is in the nucleoproteins of the cell nucleus. It produces chromosome damage with inhibition of mitosis similar to x-rays. It inhibits a large number of intracellular enzymes. In 1948, Farber (72) found that the 4-amino analogues of folic acid would produce regression of acute leukemia in children. Of thousands of drugs tested for anticancer effect, several hundred show beneficial effect in animals. The number showing beneficial effect in human beings is much smaller (Fig. 7). The more important ones being used in human beings at the present time are illustrated in Table 3.

The use and results of various chemical agents in the treatment of cancer have been discussed by Sykes and associates (73). Although many of these agents will cause regression in many patients with cancer, none of those available at the present time will cure cancer. Nitrogen mustard is quite effective in Hodgkin's disease and less so in other types of lymphomas. It will often cause regression in carcinoma of the lung (74). Triethylenemelamine is often effective in Hodgkin's disease, other types of lymphomas, and leukemia. Thio–TEPA will often produce prolonged remissions in chronic leukemias (73); likewise, it is often effective in carcinoma of the breast and ovary (75). Details of the more recent use of chloramubucil and other alkylating agents may be found in the Proceedings of the Alkylating Conference (76) held in 1957.



The importance of nucleic acid anabolism in chemotherapy has been emphasized by Rhoads (77). He calls attention to the fact that nucleic acid is a vital part of all cells and that cancer cells contain more nucleic acid than normal cells. Nitrogen mustard, which is one of the more effective chemical agents in the destruction of cancer, exerts a very destructive effect on nucleic acid, even in a high dilution. Also it is known (Herriott, 1951) that ionized radiation, the best physical agent available for the treatment of cancer, depolymerizes nucleic acid. Furthermore, chromosome abnormalities have been described in cancer cells, and nucleic acid is known to be a very important constituent of the chromosome.

ALKYLATING AGENTS



ANTIMETABOLITE

Nitrogen Mustard

6-Mercaptopurine

Fig. 7. Three examples of anticancer agents used in the treatment of human cancer.

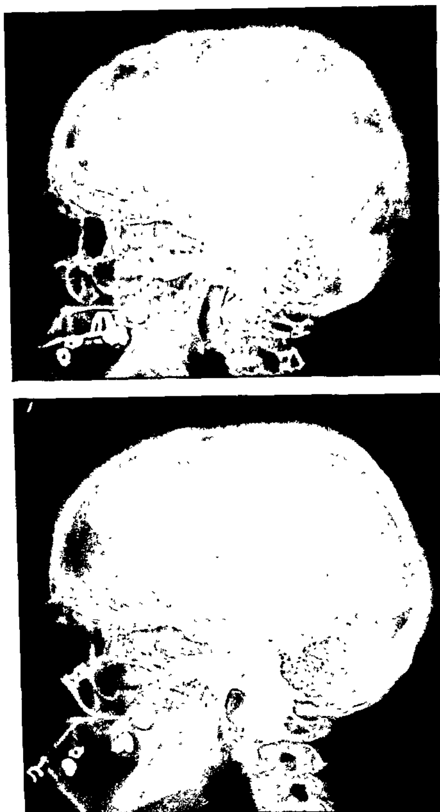

Fig. 8. Osteolytic lesions of the skull (due to metastases from a carcinoma of the breast) obliterated by bilateral adrenalectomy and oophorectomy. Above, the skull reveals innumerable destructive lesions. Below, eighteen months after bilateral adrenalectomy and oophorectomy all the lesions have disappeared. However, permanent remission is not expected.

Adrenocorticotropic Hormone (ACTH)	I.V. or I.M.	25–50 mg. by continuous infusion (10–20 mg. every 3 hr.)		
		Radioactive Isotopes		
Iodine (I^{131})	Oral, I.V.	100–200 mc.	None	Myxedema, bone-marrow depression, renal damage.
Phosphorus (P^{32})	Oral, I.V.	3–7 mc.	None	Bone-marrow depression.
Gold (Au^{198})	Intrapleur.	75 mc.	None	Bone-marrow depression.
	Intraabd.	75 mc.	None	Bone-marrow depression.
		Miscellaneous Drugs		
Urethane	Oral	2–4 gm. daily	N.&V.*	Bone-marrow depression.

* N.&V. = Nausea and vomiting

Hormone Therapy. The use of hormones in anticancer therapy constitutes "chemotherapy," but treatment with these substances is discussed separately since they are vitally different than the chemicals described above.

It has been known for decades that castration is occasionally very beneficial in cancer of the prostate and cancer of the ovary. The work of Huggins early in the 1940's advanced this knowledge appreciably. Huggins has shown that castration is definitely effective in producing regression of certain tumors (prostate and breast), and that administration of estrogen to male patients with carcinoma of the prostate results in pituitary inhibition with testicular atrophy, thus equivalent to castration. Huggins and associates (78, 79) likewise have demonstrated that bilateral adrenalectomy produces regression in certain tumors (particularly carcinoma of the breast) and may relieve symptoms for several months, although no patients have been cured by this procedure (Fig. 8). Hypophysectomy (80, 81) is also effective in producing regression of certain tumors, particularly carcinoma of the breast. Adrenal steroids have an inhibitory effect on certain tumors, primarily those involving the lymphatic tissue (e.g., leukemia).

Use of Viruses as an Anticancer Agent. The use of these agents in the treatment of cancer is more recent than of those mentioned above. Actually, not enough data have been accumulated to indicate how effective they might be. However, of the numerous viruses tried experimentally, 11 have been effective in inhibiting the growth of one or more tumors (3). Among these agents, the Russian encephalitis virus, the Bunyamera virus, and the Egyptian 101 virus seem to offer the most promise.

RESULTS

As has been stated previously, surgery and radiation are the only forms of therapy which result in cure of cancer. The various forms of chemotherapeutic agents, including the alkylating agents and hormones, will often cause a regression of the tumor for a few months or longer, but no cures have been reported; on many occasions, life has been distinctly prolonged (Table 4). Particularly is this true in leukemia which is treated by alkylating agents and antimetabolites, often alternating, because the disease tends to become resistant to one agent after a few weeks.

Summaries of reports presented at the Third National Cancer Conference in 1957 indicate that progress is being made in the cure or five-year survival rate. For example, Hammond (82), who analyzed the entire data presented for malignant tumors (exclusive of carcinoma of the skin, the most favorable of all) in various regions of the body, reports that several years ago we were saving one out of four persons who contracted the disease, whereas now we are saving one out

TABLE 5. Resectability Rate, Five-Year Survival Rate, and Operative Mortality Rate (Expressed in Percentages) After Resection for Tumors in Various Regions of the Body

(These figures combine charity and private cases. The operability and five-year survival rates are lower in the former, and the operative mortality rate higher; the reverse is true for private cases.)

	Resectability*	Five-Year Survival Rate of Resectable (Favorable Cases)	Mortality Rate for Resected Cases
	%	%	%
Bladder	65	60	5
Breast—total	80	50	0–0 5
without axillary met.		75	
with axillary met.		35	
Cervix Uteri	40	30–45	1–3
Colon	80	55	3
Corpus Uteri	90	65	0.5
Esophagus†	30	5	15
Gallbladder	10	5	10‡
Bile Ducts	30	10	3
Kidney	75	50	4
Larynx	85	50	4
Lung	30	25	7
Melanoma	70	40	1–3
Ovary	50	35	0–1
Pancreas	25	1–3	20
Prostate	15	45	3
Rectum	80	50	3
Skin	95	95	0
Stomach	25	25	6§
Tongue	70	30	5–10

* Meaning no residual tumor after resection.
† Excluding extension of gastric Ca into esophagus.
‡ Including partial resection of right lobe of liver.
§ About 10 per cent for total gastrectomy.

process, either host resistance or virulence of the cell, changes (usually fairly rapidly) and microscopic nests which have been lying dormant flare up and begin to grow.

Unfortunately tumors in many areas grow very rapidly and are not curable at the time of operation, although they may be resectable. Carcinoma of the stomach, esophagus, and pancreas are examples. Also, no more than 25 per cent of the patients with carcinoma of the esophagus and pancreas are resectable, without residual tumor, by the time the patient is operated on.

In Table 5 we have listed the tumors commonly treated by operation and have indicated their rate of resectability, percentage of five-year survival, and the operative mortality rate. The figures represent estimates or an average derived from a large number of articles in the medical literature (83–104).

Again, we emphasize that the technic for operation for cancer must be different from other operations. Resection must be wide, removing as much adjacent nonvital tissue as possible and excising all involved resectable lymph nodes. The necessity of lymph node resection is exemplified by the publication by Meyer and Gumport (103) dealing with malignant melanoma. They reported a five-year survival rate of 41.5 per cent in 65 cases. Of these, 40 had regional node dissection along with removal of the primary, with a five-year survival rate of 52.5 per cent. The survival rate was 33.4 per cent for the patients having positive nodes and 66.7 per cent in those having negative nodes. This wide difference between the five-year survival rate of patients with and without positive nodes exists in almost every tumor treated by operation, i.e., the results are almost twice as good in patients having negative nodes as it is in patients having positive nodes.

TABLE 4. Neoplastic Diseases Responding to Chemotherapy

(Modified from Karnofsky in CA—A Bulletin of Cancer Progress, 5:171, 1955)

DIAGNOSIS	USEFUL AGENTS	RESULTS
Acute Leukemia Children	Amethopterin, 6-MP, 6-MP +Azaserine, Adrenocortical hormones	70% bone-marrow improvement; 50% of patients live one year or longer
Adults	Adrenocortical hormones, 6-MP, Amethopterin	15–25% improved for several months or longer
Chronic Myelocytic Leukemia	Myleran, TEM, HN_2, 6-MP, P^{32}	Patients maintained in good condition during major portion of disease; life occasionally prolonged
Chronic Lymphatic Leukemia	TEM, P^{32}, Adrenocortical hormones	Patients maintained in good condition during major portion of disease; life occasionally prolonged
Hodgkin's Disease	HN_2, TEM	Occasional favorable response, but no definite prolongation of life
Lymphosarcoma	HN_2, TEM	Occasional favorable response, but no definite prolongation of life
Multiple Myeloma	P^{32}, I^{131}, Adrenocortical hormones, Urethane	Symptomatic relief in about 50% of cases, and objective hematological improvement in 15%
Polycythemia Vera	P^{32}, TEM, HN_2	Prolonged clinical remissions, particularly with P^{32}
Carcinoma of Lung	HN_2, TEM, Au^{198}	Brief improvement in about 50% of cases
Carcinoma of Ovary	TEM, HN_2, Au^{198}, Thio-TEPA	30–50% of cases improved for 1 to 3 months, sometimes longer
Carcinoma of Thyroid	I^{131}	Frequent marked improvement in properly selected cases
Carcinoma of Breast	Estrogens, Androgens, Thio-TEPA, Au^{198}, TEM, HN_2	20–50% improved by hormonal therapy; life may be prolonged in some cases
Carcinoma of Prostate	Estrogens, Au^{198}	80% of cases respond to hormonal therapy; definite prolongation of life
Miscellaneous Carcinomas and Sarcomas	HN_2, TEM, Thio-TEPA, Au^{198}	In rare instances, favorable responses occur

of three. These figures indicated, however, that very little progress has been made in carcinoma of the stomach, lung, esophagus, ovary, and pancreas. Perhaps the most improvement has been made in carcinoma of the cervix.

In a discussion of results, it must be made clear that the five-year survival rate, which is commonly used as the standard for results, means survival and not cure. It must be admitted that more than just a few patients who are entirely well at the end of five years will develop metastases months to years later and die of their cancer. This indicates that some

FRACTURES, DISLOCATIONS, AND SPRAINS: GENERAL CONSIDERATIONS

R. Kirklin Ashley and LeRoy C. Abbott*

GENERAL CONSIDERATIONS

Fractures, dislocations, and sprains involve the musculoskeletal system. Occasionally other contiguous structures—such as the viscera, the central nervous system, and, at times, the special sensory organs—are implicated. Because bone, tendon, and muscle are specialized structures, particularly in the manner in which they heal, careful consideration must be given to the diagnosis and management of conditions involving them. In many instances, the function regained following injury to these structures will depend largely upon the judgment, skill, and attention to detail of the attending surgeon. Frequently, impaired function is quite obvious, not only to the patient but to the layman as well.

FRACTURES

Definition. A fracture is a break or interruption in the continuity of bone or cartilage.

Classification (1). Based on the Number of Fragments. When a bone is broken into two parts, it is generally referred to as a *complete* fracture, provided the bone is completely divided; or an *incomplete* fracture, if the bone is not entirely divided. If the bone is fractured into *more than* two fragments, it is then referred to as a *comminuted* fracture. A *greenstick* fracture is an incomplete fracture commonly seen in childhood.

Based on Integumental Covering. *Closed* fractures are those in which there is no communication between the fracture site and the external environment. *Open* fractures are those in which there is such communication. Ordinarily, an open fracture is considered to be one in which the skin is broken and the bone protrudes, or at some time has protruded, through the skin. However, it must be borne in mind that a fracture of the mandible which enters a tooth socket is also an open fracture, even though it is the mucous membrane rather than the skin through which communication with the external environment occurs. In the older terminology, the word "compound" was used instead of the now accepted term *open*, and the word "simple" instead of *closed*.

Based on the Appearance of the Fracture. Transverse fractures occur when the fracture line is at right angles to the longitudinal axis of the bone. *Longitudinal* fractures (less common) follow the long axis of the bone and are a splitting type of injury, as seen when a piece of kindling is split. A *spiral* fracture twists around the bone as it proceeds along the longitudinal axis, as the name spiral implies. An *oblique* fracture occurs obliquely to the longitudinal axis of the bone (Fig. 1).

Based on the Mechanism of Injury. In *direct force* fractures (Fig. 2), that portion of the bone to which the force is applied is the site of the fracture. An *indirect force fracture*

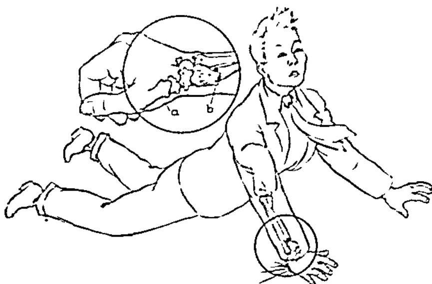

Fig. 3. A Colles' fracture. Note the patient falls with impact at point a; fracture occurs more proximally at point b.

taneously as, for instance, in the area of a metastatic tumor. In such instances the term *pathologic fracture* is applied (Fig. 4). Pathologic fractures can also occur in many other diseases of the bone—such as Paget's disease—in hyperparathyroidism, as a result of impaired nerve supply, in tabes dorsalis, in syringomyelia, in transverse myelitis, and in spina bifida.

Based on Eponym. Fractures may be classified according to the illustrious surgeon who first described that particular fracture under discussion, and in such instances the eponym is applied. Learning the various types of fracture then, becomes a matter of rote and memory: Colles' fracture, a fracture of the radius near the wrist; Pott's fracture, a special type of fracture about the ankle; Malgaigne's fracture, a special fracture involving the pelvic girdle. It is beyond the scope of this chapter to discuss these particular fractures in any detail.

Etiology. There are many factors which contribute to the etiology of fractures. The most common of these is trauma. Contributory factors are *sex*, fractures being more frequent in men probably due to greater vocational hazards. *Age* is also a contributory factor, most fractures occurring in about the third decade when persons are younger, more active, more continuously exposed to occupa-

Fig. 4. X-ray showing fracture through a simple bone cyst occurring in midshaft of the femur in a boy aged 10 years. The fracture occurred when the patient turned over in bed.

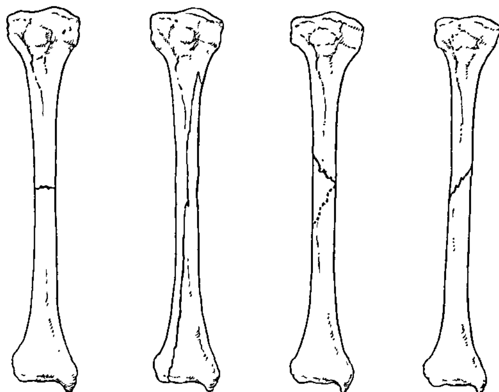

Fig. 1. The common types of fracture designated according to the appearance of the fracture line.

Fig. 2. Common type of direct force injury resulting in isolated fracture of the ulna precisely at the point of impact.

(Fig. 3) is one in which the fracture site will occur at some point distant to the application of the force. In *avulsion fractures*, interrupted bony continuity results following muscle or ligamentous pull at the site of either their origin or insertion.

It is impossible to emphasize adequately enough the importance of understanding the *mechanism of injury* since, in many instances, it is the key to reduction by manipulation.

Based on Location. According to the anatomic location of the fracture site on the bone, certain classifications may be made; for instance, a fracture of the shaft, the condyle, the tuberosity.

In the growing bones of childhood, special terms are used: i.e., a fracture of the shaft of a long bone is referred to as a fracture of the diaphysis. A fracture of the diaphyseal side of the epiphyseal plate is referred to as a metaphyseal fracture. A fracture through the epiphysis is called an epiphyseal fracture.

Based on the Status of the Bone Structure Prior to Fracture. The majority of fractures are traumatic. Not infrequently, however, a fracture may occur spon-

union, the bone is gradually strengthened and the callus resorbed. If satisfactory position of the bone has been obtained and restoration has been normal, it is often difficult later to determine the exact site of the fracture, especially in children. Remodeling takes place as a result of the stress and strain of use and muscle pull, and the final shape of the bone will depend upon the internal and external stresses applied. The time required for each stage of the healing process is governed by many variables. For a more detailed description of fracture healing, the reader is referred to the excellent section on the healing of fractures in A. W. Hamm's *Histology* (3).

Diagnosis. HISTORY. A careful and detailed history should be obtained from the patient or, in cases where the patient is in no condition to give such a history, by those who accompany him. Particular and careful effort should be made to learn the precise mechanism of injury. Many times it is the first impulse of the patient to say that the injury occurred with such speed that it is impossible for him to recall exactly what mechanism was involved. Unless intoxicated or unconscious as a result of the injury, however, most patients on careful questioning are able to give a fairly accurate description of this mechanism, despite their first statement that they fail to remember it. They will then describe it as a direct force, a twist, a fall backward or forward, to the right or to the left side. It is not uncommon to elicit a history of deep, aching pain which has continued for a period of several weeks or months prior to the time of fracture in cases of pathologic fracture.

Point Tenderness. Point tenderness is invariably noted in fractures and is exactly what the name implies. The injured area is gently palpated with the finger or examined with the blunt point of a pencil. At one point, the examiner will encounter exquisite tenderness. That point is the exact fracture site.

Deformity. There is obvious deformity in fractures where there has been considerable disarrangement of the part. Many times there is marked soft tissue swelling which obliterates deformities of less magnitude. By very gentle palpation, even small amounts of deformity can be noted. It is extremely important that most careful and gentle palpation be employed because of the severe amount of pain which can be brought about by heavy-handedness on the part of the examiner. This pain is of such an intense and deep-seated nature that it can produce marked shock.

Crepitus. Crepitus is a grating which can be heard or felt when the rough, bony fragments rub against each other. It is often not elicited when there is interposition of soft parts. It may be simulated by such other conditions as movement of a roughened joint surface adjacent to the fracture, subcutaneous emphysema, or tenosynovitis.

Abnormal Mobility. The presence of abnormal mobility is pathognomonic of fracture. In fractures which occur near a joint, however, it is necessary to distinguish abnormal mobility at the fracture site from the normal mobility of a given joint.

Pseudoparalysis. This is a term which is given to the loss of function which may accompany fractures. It is seen most classically in children. It is due to loss of mechanical support and of mechanical advantage of muscles, plus marked pain on attempted motion. Unfortunately it is not a reliable physical finding, since it may also accompany contusions, sprains, and other injuries. It may sometimes be hysterical in nature.

Auscultation and Percussion. Occasionally, when one is unable to elicit crepitus by gentle palpation, it can be heard with the use of a stethoscope applied locally. If there is loss of contact of the bone end, auscultation can be a valuable adjunct in diagnosis. For example, the stethoscope is placed on the symphysis pubis. The patella is then tapped with the finger, and an osteal ring is heard. If, however, the opposite patella is tapped and there is a fracture of the hip with loss of contact, or poor contact, an osteal ring will not be heard. Instead there will be a muffled sound, which is readily distinguishable from the ringing sound characteristic of the normal uninjured side.

Local Swelling. Following fracture, the *immediate* swelling is due to hemorrhage. Further swelling usually occurs later. This is the result of inflammatory exudate and impaired drainage of blood, lymph, and extracellular fluid.

Nerve and Blood Supply. Particularly careful evaluation of the nerve and blood supply to the distal portion of a fractured

tional hazard, engaged in athletics, and, in general, less cautious. However, it is well known that fractures may occur in intrauterine life—during the passage down the birth canal or in the course of delivery—or at any other time during life from infancy to far-advanced years. *Pathologic conditions of bone*, as has already been mentioned, may so weaken it as to be considered an etiologic factor.

Pathology and the Repair of Fractures (2). In the normal bone, healing begins immediately following fracture. Under auspicious conditions, the fracture progresses through five stages until consolidation of the bone occurs (Fig. 5). These stages are: 1. hematoma; 2. granuloma; 3. callus; 4. consolidation; 5. remodeling.

1. *Stage of Hematoma.* When fracture first occurs, blood oozes through lacerated vessels and a hematoma is formed, which bathes the fractured bone ends and brings about a continuity by means of the pool of blood. The periosteum and muscles, which are often torn from the bone ends to a variable extent, surround the hematoma.

2. *Stage of Granuloma.* The hematoma now undergoes organization. The organized hematoma is invaded by a network of capillaries which grow into it from the surrounding tissues. The organized hematoma containing a capillary network is, at first, a friable type of granulation tissue, which gradually becomes firmer and forms an elastic union between the bone surfaces.

3. *Stage of Callus.* The repair site is now entered by osteoblasts, and callus ensues. Callus lacks the typical lamellar structure characteristic of mature bone and has been termed "woven bone." Clinical examination at this stage will reveal a growing firmness at the fracture site. When the mineral salts are deposited through the action of the enzyme alkaline phosphatase, the fluffy white shadow characteristic of a healing fracture is visible by x-ray.

4. *Stage of Consolidation.* With the passage of time this callus, or woven bone, is transformed by osteoblastic activity and results in typical mature bone with characteristic lamellar structure.

5. *Stage of Remodeling.* The last stage, remodeling, is exemplified by the formation of a rounded excrescence on the outer surface of the healing bone. This not only forms a collarlike protuberance which surrounds the bone but also obliterates the medullary canal within. Where the periosteum has been stripped to a considerable degree and the fracture hematoma is large, with marked displacement of fragments, the size of the excrescence will be proportionately large. With a lesser degree of derangement from the norm, the excrescence may be smaller; the size varies from case to case. In children, there is usually abundant callus. Following

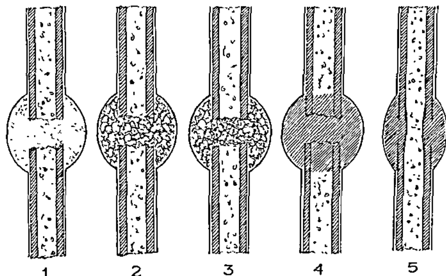

Fig. 5. Schematic drawing of the five stages of regeneration of the bone. 1, Hematoma; 2, granulation; 3, callus; 4, consolidation; 5, remodeling. (From Adams, J. C. Outline of Fractures, E. & S. Livingstone, Ltd.)

X-ray studies must include an anteroposterior view, as well as a lateral view (4) (Fig. 6). Occasionally, additional views will be necessary in certain types of fractures, particularly in those fractures which occur around or near the joints and are apt to have involved the articular surface of a joint. In no case, however, is one view ever sufficient.

Furthermore, because of the presence of epiphyseal plates of irregular outline in childhood, there is occasional confusion with the presence or absence of a fracture line. Therefore in children, x-rays of the *opposite, uninjured member for comparison* with the injured side must be taken. In certain instances, x-ray studies must be repeated after an appropriate time interval, perhaps of two or three weeks, in order to clarify the presence or absence of fracture. Particularly is this true of linear, undisplaced fractures which involve the small bones of the wrist, the ribs, and sometimes the neck of the femur. This is also strikingly seen in fatigue fractures (march fracture) of the metatarsals. An x-ray taken shortly after the injury may appear to be normal. Two to three weeks later, however, a repeat study may demonstrate some healing reaction or an obvious fracture line where none was evident before (Fig. 7). The fracture line will appear in the later study because of the hyperemia and resultant demineralization at the fracture site, which was not evident at the time of the original study. During the period between the two x-ray studies, the condition should be treated as though it were a fracture.

Fig. 7. Showing importance of second x-ray taken subsequently when diagnosis is in doubt. Above, normal x-ray of foot (patient complaining of pain in metatarsal); left, film of same foot two weeks later showing callus formation about a typical "march fracture" of the third metatarsal neck.

In the clinical differential diagnosis between a fracture and a dislocation, in instances of *fracture* there is *abnormal mobility,* where there should be *no mobility.* In

extremity must be made because of the serious consequences which may result from the impairment of these two vital functions. Any impairment of these structures should be carefully noted prior to reduction. Thus it will be ascertained that residual vascular or neurological deficit has been the result of the injury itself.

Systemic Reaction. Following fracture, a slight fever of one or two degrees will often be noted. During the first 24 hours there may also be a polymorphonuclear leukocytosis. These conditions are especially marked in childhood.

There is no substitute for a careful history and physical examination of the whole patient if an accurate diagnosis is to be made. These two steps—history and physical examination—are equally as important in the management of traumatic injuries as they are in all other phases of clinical medicine and surgery. Following careful clinical examination, radiologic examination of the injured member is mandatory. Prior to sending the patient for radiologic examination, immobilization of the fractured part should also be routine. This is of the utmost importance, and will be discussed later under "Treatment."

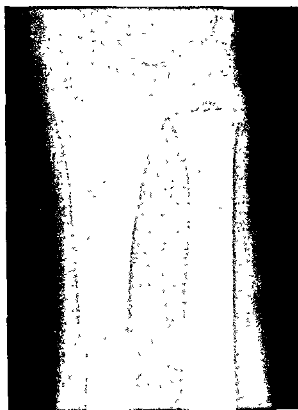

Fig. 6. Showing importance of obtaining anteroposterior and lateral views. Left, anteroposterior film showing acceptable alignment; below, lateral view showing marked and unacceptable angulation.

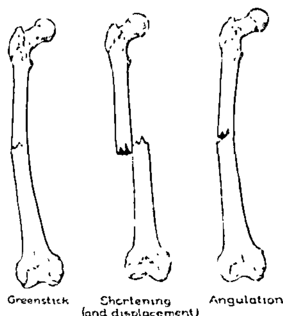

Fig. 8. Types of deformity seen in fractures.

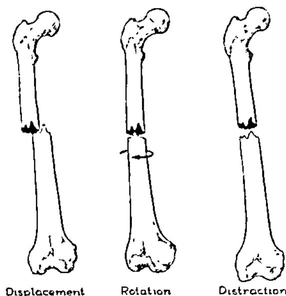

Fig. 9. Types of deformity seen in fractures.

following the injury (8). This will not delay union or impair functional results. If this procedure of so-called "delayed-reduction" is carried out, the extremity must be supported in a plaster of Paris splint during the interim. Two factors which may advise delayed reduction are: 1. critical condition of the patient; and 2. excessive swelling of the injured member. Contraindications to delayed reduction are the presence of nerve injury, vascular injury, dislocations, and open fractures.

METHOD OF REDUCTION. *Closed Reduction.* The ideal method of reduction is that of closed manipulation of the fracture, provided accurate reduction and satisfactory maintenance of reduction can be obtained by this technic (9). In order to obtain an accurate reduction, a careful analysis of the deformity first must be made. Various deformities which may occur are: shortening, displacement, angulation, rotation, and distraction (Figs. 8, 9). Frequently they exist in combination. When reduction by manipulation is performed, correction of each of the existing deformities should be carried out in an orderly fashion. It is here that large dividends are paid by having a thorough understanding of the mechanism of injury and by having analyzed carefully the various deformities prior to the time of reduction. For each deformity a force must be applied in the direction *opposite* to it in order to obtain accurate and orderly reduction. If there is shortening, traction is its correcting or reducing force. Constant, steady, nonvibrating traction prior to manipulation may aid in securing reduction, by diminishing muscle spasm and shortening. If there is displacement laterally, then force medialward is the reducing force. In the same fashion, angulation, rotation, and distraction deformities may be corrected.

Open Reduction. Open reduction is utilized when the closed method fails to give reduction or fails to provide adequate stability, necessitating the use of internal fixation. It should be used only by individuals who have been carefully trained in its intricacies and who are thoroughly familiar with its management and possible complications (10). Open reduction and internal fixation are also used in the presence of certain pathologic conditions of bone which preclude the use of prolonged bed rest. This is seen, for example, in the elderly patient who has Paget's disease as well as a fractured femur. The use of open reduction and an intramedullary rod is justifiable in such patients, even though adequate reduction and fixation might have been obtained by the closed method. Prolonged bed rest in such a patient frequently results in mobilization of large amounts of calcium from the diseased skele-

cases of *dislocation* there is *restriction in mobility,* where there should be *free mobility.* Here again, x-ray diagnosis is of prime importance and is necessary in order to protect the patient and to serve as a record in the event of future litigation.

Because this chapter is devoted to a discussion of fractures, dislocations, and sprains, the reader's attention is more specifically directed to a local area of injury. However, nothing can be more dangerous than to limit attention to the "local area." The entire patient should be examined. The examiner should be constantly on the alert to the possibility of the presence of multiple fractures and injury to the adjacent structures, the treatment of which may take precedence over that of the bone (5). For example, in fracture of the pubic portion of the pelvis, injury to the bladder or membranous portion of the urethra is of far greater immediate consequence than is the interruption of the continuity of the bone. In like manner, fractures of several ribs may lead to serious consequences and jeopardize the life of the patient if the underlying lung parenchyma and blood vessels have been severely lacerated.

Treatment. SYSTEMIC. Fracture is often accompanied by shock, and immediate attention must be given to the amelioration of this condition. Details of the treatment of shock will be found elsewhere in this text. The principles of the treatment of shock are followed in the usual fashion. In addition, it must be remembered that fractures, particularly of the large bones or when multiple, are usually accompanied by hemorrhage which may amount to from 1,000 to 1,500 ml. or more of blood. In a closed fracture, this hemorrhage occurs into the soft tissues, and, though it is not lost from the body, it is lost from the effective circulating blood volume and should be replaced by transfusion as quickly as possible.

LOCAL. Immediate immobilization of the injured part can prevent further injury and also help to control shock (6). There are many forms of immobilization, the simplest perhaps being the plaster of Paris cast which has the advantages of being readily available and made to order for the patient, thus providing a perfect fit. There are, in addition, padded cardboard splints, metal splints, pillow splints, and the opposite extremity, in the case of a leg, which offers a good splint.

In order to secure satisfactory union of the fracture, certain fundamental criteria must be met. They are *bone contact, adequate immobilization, good blood supply,* and *absence of infection.* Of these fundamental criteria three—bone contact, immobilization, and absence of infection—can be controlled and modified by the physician. The fourth, good blood supply, is in most instances beyond the control of the physician. There are certain fracture sites that have been recognized as having poor blood supply, for example, the junction of the middle and distal thirds of the tibia and the shaft of the ulna. It is important to have some knowledge of these poorly vascularized areas, since the time required for union to occur at these sites is usually quite prolonged. When union is slow to occur, the surgeon, being conversant with the situation, will persist in conservative measures rather than resort to the more radical ones, which may not better blood supply and therefore not attack the basic problem (7). Assuming that the four fundamental requirements have been met, union can practically be assured. However, union does not, of itself, imply an entirely satisfactory result. The union must occur with the bones in a satisfactory position, and the joints must be freely mobile; muscle power too must be regained in order to consider the result perfect. Therefore, the treatment of a fracture includes the classical "three R's"—Reduction, Retention (or immobilization), and Rehabilitation.

Reduction. Accurate reduction of a fracture, or "setting the bone," is necessary in most fractures which show any degree of deformity. There are, however, certain exceptions, as will be discussed in later chapters. To obtain satisfactory reduction in most cases a general anesthetic, regional anesthetic, spinal anesthetic, or some similar form of anesthesia is required. This is necessary if adequate muscle relaxation is to be obtained so that successful manipulation can be accomplished.

TIME OF REDUCTION. Under ideal conditions, the best time to reduce a fracture is as soon as possible following the diagnosis. It has been shown that a fracture may be reduced at any time during the first 14 days

Fig. 11. Anteroposterior and lateral views showing internal fixation of comminuted spiral fracture at junction of middle and distal third of tibia by means of two screws. Additional plaster immobilization is necessary.

When the extremity is released from the cast or other fixation appliance, increased efforts must be directed toward mobilizing the previously immobilized joints and strengthening the weakened muscles. There is no substitute for active exercise in accomplishing these two important steps. Massage, warm compresses, and soaks are many times comforting and of psychologic benefit, but they will never strengthen a muscle nor mobilize a joint. Here again, special exercises must be prescribed by the surgeon. He should be sure that the patient understands what is required of him, by having the patient perform his exercises on several subsequent visits. The physical therapist can be of great value, but it is the direct responsibility of the surgeon to prescribe exercises and other forms of treatment to be given by the therapist, and also to see that these are carried out meticulously. Rehabilitation plays an integral part in the treatment of traumatic injuries, and it is the duty of the attending surgeon to make use of all of its facilities in his effort to return the patient to the highest functional level (4).

Special Treatment of Open Fractures. Because of the communication with the external environment at the fracture site, infection may occur in the case of open fractures. Infection may impede or mitigate against union. Therefore, special attempts to avoid such complications must be made in the case of open fractures. If the fracture is seen within six hours of the time of injury, immediate débridement of the wound in the operating

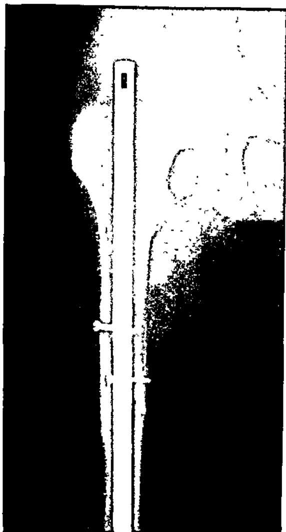

Fig. 10. Internal fixation of comminuted fracture of femoral shaft by means of intramedullary rod and two screws.

ton. This, in turn, produces hypercalcemia, and places an extra demand upon the kidneys. Occasionally, the kidneys are unable to meet this demand, and the so-called "hypercalcemic death of Paget's disease" may ensue.

Immobilization. Fixation can be obtained by four methods: 1. external fixation, consisting of a plaster of Paris cast or other adequate splint; 2. internal fixation: nails, intramedullary rods, screws, plates, pins, and the like (Figs. 10, 11); 3. a combination of internal and external fixation, consisting of pins in the proximal and distal fragments incorporated in a plaster cast (fixed traction) (Fig. 12). The Stader (11) or Roger Anderson type of external fixation splint, in which pins are applied to the proximal and distal fragments and then incorporated into a rigid connecting frame, has been used successfully (Fig. 13). 4. Balanced traction, which consists usually of skeletal traction on a pin introduced below the fracture site (in the tibial tubercle in the case of a fractured femur). Traction is used to overcome the pull of the deforming muscles, and, in the case of balanced traction, the extremity is usually supported in a cradling splint—such as a Thomas splint, or Böhler frame—and the traction applied by means of weights and pulleys. It is possible to maintain reduction in certain fractures using skin traction, but not in the case of most of the larger bones. The choice of the preferred method of treatment will be discussed under specific fractures in later chapters of the text.

Rehabilitation. In the foregoing, the first two of the "three R's of fracture management," namely reduction and retention (or immobilization) have been discussed. It is of the utmost importance always to keep in mind that the entire effort of the surgeon is directed toward returning the injured patient to the highest possible level of functional ability. Often it is tempting to lose sight of this ultimate goal, and to concentrate only on the treatment of an x-ray film or on the localized treatment of the fractured bone itself. From the very earliest stages of management, attention must be directed toward the mobilization and active exercise of all joints and muscles that are not, of necessity, immobilized because of the fracture. Regular exercise periods throughout the waking hours are of great help in preventing joint stiffness and the atrophy of disuse. The patient must be instructed in what he is to do, and subsequently must be asked to demonstrate his exercises. It is only in this way that the surgeon can be assured that his instructions have been well understood by the patient.

A patient who has fractured his left tibia and is confined to bed for 10 days to two weeks will be benefited by regular exercises to the uninjured leg, deep breathing exercises, and muscle strengthening exercises to the upper extremities and to the hip on the injured side. When he is allowed to become ambulatory, the usual weakness which accompanies bed rest will largely have been circumvented, and unnecessary and expensive hospital time spent in regaining strength will have been avoided.

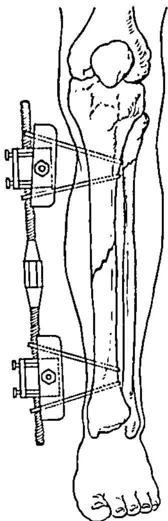

Fig. 13. Immobilization of fracture by means of external bar fixation.

x-ray, separation of the fragments but with no sclerosis of the bone ends, and no false joint.

Etiology of Delayed and Nonunion. The most common cause of delayed union and nonunion is inadequate immobilization. Interruption in blood supply accounts for other cases; lack of bone contact for some; and the presence of infection for still others.

Treatment of Delayed and Nonunion. In cases of nonunion, where there is actual sclerosis of the bone and a false joint, the treatment must be surgical if union is to be gained. This consists of freshening the sclerotic bone ends, of bridging the site with bone graft (13, 14, 15), and rigid immobilization or fixation. The type of immobilization or fixation must be adapted to the individual case. Delayed union, when it occurs, sometimes may be treated successfully merely by prolonging the period of immobilization. Occasionally, attempts are made to bring increased blood supply to the local area by means of multiple drilling of the proximal and distal fragments. The simple onlay bone graft of Phemister (16) has been used with success for many years. In the majority of cases of delayed union, the simplest and least traumatic procedure will give the most gratifying results.

STIFFNESS IN JOINTS. This complication is frequently the result of inadequate instruction to the patient concerning proper exercises during the period of convalescence. It may occur also as a result of splinting a joint in a position of strain. Stiffness may be the unavoidable result of severe fractures involving articular surfaces. Severe injury to the muscles and tendons scarred down by the healing process of a fracture, even though distant from the joint, may impair the function of that joint. This is seen particularly in fractures of the shaft of the femur, resulting in some unavoidable degree of limitation of motion in the knee joint (17).

MALUNION. As the name implies, malunion occurs when a fracture unites in a position of deformity. The causes here are inadequate reduction, inadequate fixation, mobilization prior to solid bony union, or unrecognized loss of reduction. The best treatment is prophylactic. Careful follow-up roentgen examination until union has become sufficient to assure maintenance of position is imperative and, in many instances, will obviate the embarrassment of malunion. Where it has occurred, malunion is usually treated by osteotomy and correction of the deformity.

DISLOCATIONS

Definition. Dislocation is a persistent displacement of the articular surfaces of a joint from the normal functional position (Fig. 14).

Pathology. ACUTE TRAUMATIC. Acute traumatic dislocation is characterized by a forceful stretching of a joint beyond its normal range of motion until there is tearing of the synovial and fibrous capsule and protru-

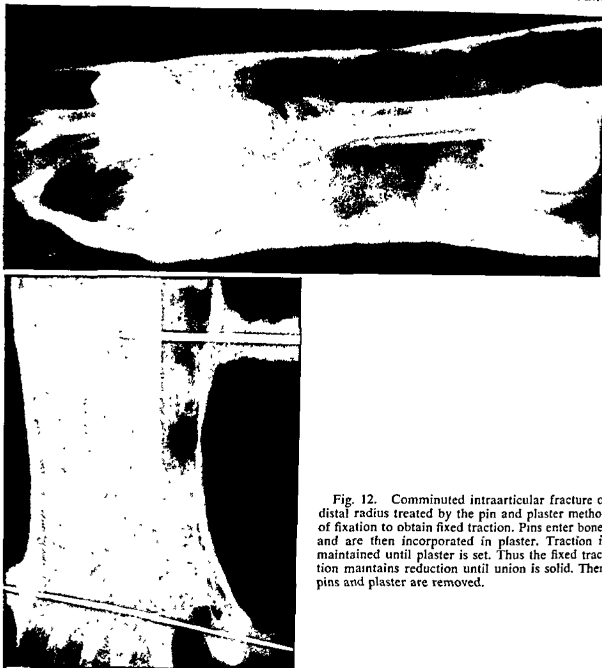

Fig. 12. Comminuted intraarticular fracture of distal radius treated by the pin and plaster method of fixation to obtain fixed traction. Pins enter bones and are then incorporated in plaster. Traction is maintained until plaster is set. Thus the fixed traction maintains reduction until union is solid. Then pins and plaster are removed.

room, with removal of devitalized tissue, dirt, and other foreign material, permits primary closure of the wound. In such cases, the percentage of successful results is high, especially with adequate systemic antibiotic therapy. Open fractures seen later than six hours after they have occurred should also be treated by débridement, but are better left packed open with vaseline gauze after reduction and then immobilized in plaster (12). Secondary closure may be attempted later. The appropriate time for secondary closure is when there is no longer danger of infection or, if infection has occurred, when it is under satisfactory control. Vigorous antibiotic therapy should be employed routinely in the management of these late cases, as well as in those seen prior to the optimum six-hour period.

Complications. NONUNION. Established nonunion is apparent when there is sclerosis of the fractured bone ends with bone laid down along the fracture line on the proximal and distal fragments and the formation of a false joint.

DELAYED UNION. Delayed union is characterized by persistence of the fracture line on

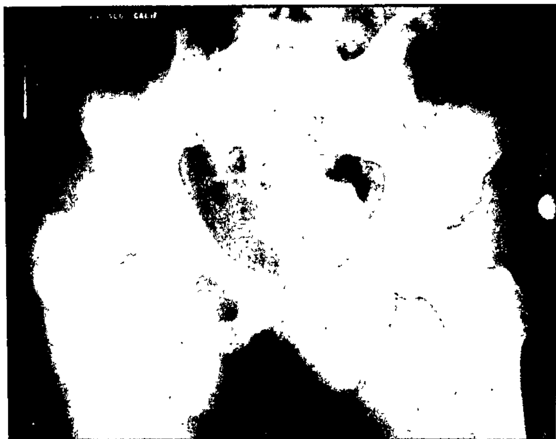

Fig. 16. Fracture dislocation of hip sustained in automobile crash. Patient was sitting with knee and hip flexed and struck patella on dashboard. Dislocation could not be reduced by traction without flexing hip.

tinuous muscle spasm about the involved joint; and point tenderness is not as striking as that seen in fractures.

ROENTGEN EXAMINATION. Roentgen examination is again of extreme importance; and again, two views are necessary (Fig. 15).

Treatment. After the diagnosis has been made and shock controlled, treatment of the local condition is undertaken as soon as possible. Because of the marked muscle spasm, reduction usually is accomplished with the least amount of trauma when an anesthetic is given. With the muscles relaxed, the limb should be placed in the position that it assumed at the time of the dislocation. Then gentle force should be applied in the *reverse* direction to the deforming force. This illustrates once more the importance of knowing the mechanism of injury (Fig. 16). The limb is then supported in a suitable splint until healing of the torn capsular and supportive structures has occurred. The length of time required for this healing varies with the magnitude of the torn structures but, in general, is about three weeks. The splint must be applied with the extremity in a position that will not allow recurrence of the dislocation.

The treatment of recurrent dislocation usually involves bony, ligamentous, or fascial reconstruction. It is quite detailed and can be found in other texts specifically devoted to the treatment of these injuries (Watson-Jones, 4, and Shands 9).

The treatment of open dislocations follows the general principles as set forth in the treatment of open fractures, but careful inspection must be made to ensure that no foreign bodies are retained within the joint.

SPRAINS

A sprain is a dislocation of a joint—usually partial—which has become spontaneously reduced. Partial tearing or complete tearing of the supportive fibrous, ligamentous,

Fig. 14. Subcoracoid dislocation, the most common type of shoulder dislocation.

sion through the tear of the dislocated distal or proximal articular surface. It is not uncommon that the major supporting ligaments are torn as well. Fracture of articular cartilage or adjacent bone may also occur with dislocation.

CONGENITAL DISLOCATION. Congenital dislocation is characterized by persistent displacement of the articular surfaces of a joint *without* a tear in the fibrous capsule. The most commonly seen congenital dislocation is that of the hip. Congenital dislocations are not the result of trauma.

RECURRENT DISLOCATION. In recurrent dislocation usually there has been damage to the articular rim of the adjacent structure so that the surface is flattened and shallow. Recurrent dislocation may also occur as a result of marked laxity in the fibrous supportive capsule or in the major supporting ligaments. It is characterized by repeated dislocation initiated by minimal trauma and represents basic instability of the involved joint.

Diagnosis. HISTORY. Just as in fractures, the history is a valuable tool in the diagnosis and treatment of dislocations, particularly in the importance of the mechanism of injury.

Examination. PHYSICAL. Careful physical examination is again of paramount importance, with particular attention necessary to the evaluation of the nerve and blood supply. Often shock accompanying dislocation is profound. Careful inspection and palpation will reveal that many of the characteristics of fracture are lacking. The deformity will always involve a joint rather than the bone itself. There will be no crepitus unless there is an accompanying fracture. There is marked and con-

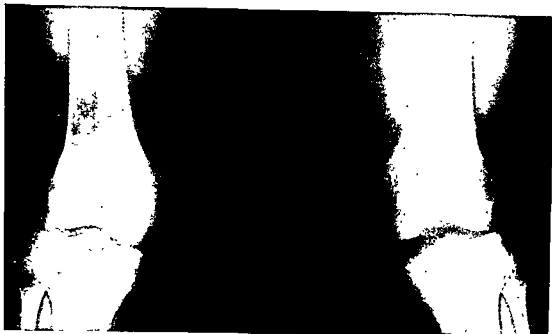

Fig. 17. Conventional x-ray studies were normal. Special x-ray shows two knees subjected to equal stress under anesthesia. The left knee demonstrates tear of medial collateral ligament.

and synovial structures usually occurs. Occasionally, the supportive ligament will avulse a chip of bone at its insertion or origin, instead of itself tearing.

The most common sprain is that of the ankle joint. Sometimes the pain is intense, but frequently it is not severe enough to prevent continued walking. However, if the patient sits down to rest for a short time, it is not uncommon that he finds, after this brief rest period, he is unable to bear weight upon the injured ankle because of the intense pain. Swelling is variable and may not appear for several hours. Ecchymoses may not appear for two to three days.

Treatment of sprains depends largely upon the severity of the injury. Cold compresses applied immediately for an hour or two will minimize the swelling. The joint should be supported in a position of maximal relaxation of the involved ligament. Frequently, this can be accomplished with adhesive tape strapping. In the more painful cases a more rigid support, such as a light plaster splint, should be used. As ligamentous healing and subsidence of pain occur, early motion is begun. When there is marked tearing and instability of the joint, surgical repair of the large supportive ligaments, particularly of such weight-bearing joints as the ankle or knee, is undertaken (18). In some cases, this can be determined only by examination under anesthesia with the aid of x-ray films taken with the joint in a position of stress. It is of prime importance to recognize these severe ligamentous tears and treat them accordingly (Fig. 17).

SUMMARY

The fundamental principles which should guide the surgeon in the diagnosis and management of fractures, dislocations, and sprains have been presented in this chapter, giving only general considerations. As A. Bruce Gill states: "Study principles rather than methods. A mind that grasps principles will devise its own methods." The usefulness of these principles will become abundantly apparent as they are applied to the diagnosis and management of specific fractures, as discussed in the ensuing chapters.

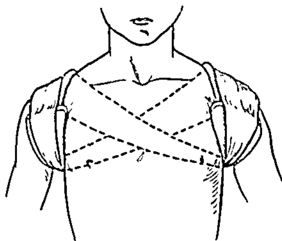

Fig. 2. Another method of immobilization in fracture of the clavicle, the figure-of-eight bandage; it is particularly useful in children. The dotted lines show how the bandage crosses on the back. The arm on the affected side is supported in a sling which is not shown.

posteriorly against the shoulder. To achieve this backward force, it is necessary to make backward pressure against both shoulders. For this reason, the Velpeau and Sayre dressings commonly used years ago for fracture of the clavicle have been abandoned; moreover, these dressings are usually very uncomfortable. Backward pressure against both shoulders with the thorax immobilized will result in satisfactory reduction in most cases. Under ordinary circumstances, the application of a figure-of-eight bandage with the shoulders held backward by assistants (Fig. 2) will maintain reduction sufficiently well to yield a good result. The axillae must be well padded with cotton and felt. A sling is necessary for the forearm on the side of injury to prevent downward displacement of the outer fragment. It will be necessary to check the dressing every two or three days to prevent dislocation of fragments.

In patients with badly displaced fragments, or in women in whom a good cosmetic result is desired, it may be desirable to apply a figure-of-eight plaster dressing which will maintain reduction more effectively. Here again, heavy padding is essential to protect the skin and axillae. As the plaster is setting, the patient should be lying supine with a small sandbag between the scapulas, and pressure should be maintained by the surgeon posteriorly against each shoulder. The cast should be trimmed to maintain pressure against the outer end of the clavicle anteriorly, but is cut away in the axilla to prevent undue pressure. The bandage or plaster cast should be left in place for three or four weeks in children and five to six weeks in adults.

On rare occasions, when displacement is marked and reduction impossible (usually because soft tissues are wedged between the fragments), an open reduction will be indicated. After reduction is achieved, position is maintained by heavy wire threaded through the medullary portion of the fragments.

In women or young ladies where the maximum cosmetic results are desired, absolute bed rest with no pillow, and with the arm in a sling offers the most satisfactory results. The patient is allowed up for bathroom privileges only. This routine, however, is very difficult to carry out because the patient will, in most instances, refuse to stay in bed. About four weeks' time is required for sufficient fibrous union to take place to prevent recurrence of the deformity; at the end of this time a Velpeau cast or bandage could be applied for further immobilization.

In transverse or oblique fractures with marked displacement, which either endangers the brachial plexus or threatens to perforate the skin, open reduction is sometimes necessary. The use of an intramedullary Kirschner wire or Rush pin is satisfactory in these cases for maintenance of reduction.

Dislocations of the Clavicle. The articulations at each end of the clavicle, though movable, are diarthroses and not true joints. Through injury of various types, the ligaments at either the acromial or sternal end may be torn. *Acromioclavicular* dislocation, however, is the more common of the two. The articular capsule is readily torn, but rarely does sufficient displacement occur to tear the coracoclavicular ligaments. If these ligaments are torn, wide displacement may occur. Examination rarely fails to disclose the true nature of the injury. The distal end of the clavicle is prominent and the acromion is depressed to a lower level. Tenderness and pain are present at this site. Abduction of the arm is painful. *Treatment* is best carried out by operative means but, if refused or impractical because of other injuries, external fixation will have to

23

FRACTURES, DISLOCATIONS, AND SPRAINS: SPECIFIC TYPES

CARLO SCUDERI

Because of the gradually increasing number of automobile accidents, and the great number of injuries sustained in innumerable other types of accidents, fractures will continue to be a serious surgical problem. Although certain types of fractures are more common than others, fractures of almost every conceivable type can be produced. The complexity of the problems of reduction, bone healing, and the like, requires much training and experience on the part of the surgeon. In this chapter we will have space to discuss only the principles. The reader is referred to texts (1, 2, 3) and monographs (4, 5) for details.

THE SHOULDER GIRDLE

Traumatic lesions of the shoulder girdle are very common and include, primarily, fractures and dislocation of the clavicle, scapula, and shoulder joint.

Fracture of the Clavicle. This injury occurs most commonly in the middle third, and is encountered more often in children than adults. It is due to a transmitted force against the lateral side of the shoulder or to a direct blow on the bone itself. The important manifestations are pain, swelling, local tenderness, and deformity at the site of fracture. In children who have sustained a fall or similar injury and are reluctant to move the upper extremity, a fracture of the clavicle should be suspected; examination will usually reveal the primary manifestations mentioned above. The deformity is characteristic, the medial fragment being pulled proximally (cephalad) and backward (Fig. 1). The weight of the extremity pulls the outer fragment forward and downward. The fracture is usually oblique and overriding; comminution is not uncommon. Diagnosis is rarely difficult because the bone is subcutaneous throughout its entire extent. If there is a displacement of fragments there will be a shortening of the distance on the side of the fracture between the sternum and acromium, as compared to the uninjured side. X-ray films in the anteroposterior view reveal the lesion perfectly. On only rare occasions is the fracture compound; other complications are also uncommon.

Treatment consists of immobilization of the shoulder with force exerted upward and

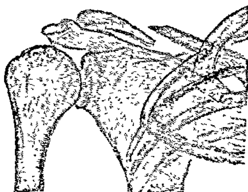

Fig. 1. Fracture of the clavicle at a common site. Sketch from an x-ray film, showing the usual displacement; the patient sustained this injury by falling on her shoulder.

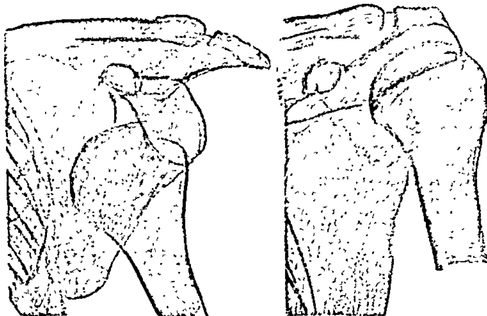

Fig. 3. Anterior dislocation of the shoulder in a 45-year-old laborer. Reduction was readily accomplished with the Kocher maneuver but recurrent dislocation finally necessitated an open operation.

hand. A characteristic sign is inability to touch the opposite shoulder with the hand of the injured side, maintaining the elbow in contact with the thoracic cage. There may be numbness of the ulnar side of the hand because of pressure of the head of the humerus on the brachial plexus. The axillary nerve may also be injured, with consequent paralysis of the deltoid muscle and inability to raise the arm at the shoulder.

Treatment consists of reduction of the displaced head. If the dislocation has just been sustained and inflammatory swelling has not occurred, reduction can be effected rather easily, but a general anesthetic is usually necessary in order to achieve muscular relaxation. The safest and most effective method of reduction is traction. Elimination of pain by ⅙ or ¼ grain of morphine will frequently be sufficient to attain reduction, although on other occasions an anesthetic will be necessary. In the traditional Kocher maneuver, which is losing favor, the upper arm of the patient is externally rotated. Reduction is then effected by adducting the arm, bringing the elbow forward and across the chest as the upper arm is internally rotated by bringing the hand of the patient over to the opposite shoulder. Another method consists of steady traction of the entire extended arm either in a longitudinal direction or at right angles to the body. After reduction, the arm is immobilized by bandaging it to the chest in a modified Velpeau fashion for two to three weeks, after which gradually increasing motion may be started. In dislocations of up to two weeks' duration the difficulty becomes greater, although reduction may still be effected in some cases up to two months. After this period, or when closed reduction is ineffectual, open operation is usually indicated. Factors leading to recurrence have been discussed by McLaughlin and Cavallaro (6).

Posterior Dislocation. This type of injury is rare; it is produced by falling upon the elbow with the arm rotated internally and abducted. The tear in the capsule occurs in the posterior portion and the head comes to rest at the posterior margin of the acromion (subacromial dislocation) or beneath the spine of the scapula (subspinous dislocation). Reduction is accomplished by down traction on the arm, and pressure on the head of the humerus in an outward and anterior direction.

Recurrent Dislocation of the Shoulder. If the tear in the capsule inflicted at the primary injury is large and healing is inadequate, the resultant scar may not offer sufficient support to prevent subsequent dislocation. *Subcoracoid* dislocations are most prone

be the method utilized. A felt pad is placed over the distal end of the clavicle and a band of adhesive anchored from the anterior chest over the pad to the back. The shoulder may then be lifted up by a strip of adhesive or modified Velpeau dressing with adequate padding under the olecranon. The outside of the dressing should be reinforced with adhesive in order to prevent stretching of the dressing with consequent loosening. To be effective, this dressing must be tight at all times and be worn for five or six weeks. It should be inspected every four or five days and reinforced or changed lest the shoulder be allowed to droop and tear the early fibrous union at the joint. Firm healing with correction of deformity is not always attained. However, the disability which follows is usually slight. Occasionally, when sufficient disability is present or when the coracoclavicular ligament has been completely torn, operative repair, requiring the use of fascial sutures or wires, may be advisable, although resection of the distal end of the clavicle is preferred by most bone surgeons.

Sternoclavicular dislocation is uncommon; when it occurs the sternal end of the clavicle is usually displaced upward and anteriorly. Tenderness and pain upon movements of the shoulder are present but not severe. If the dislocation is complete, operative repair is necessary. However, attempts at maintaining the reduction by loops of wire have usually terminated with the wire slowly cutting through the relatively soft bone, making a recurrence too frequent. Many surgeons advise resection of the proximal three-fourths inch to one inch of the clavicle; convalescence is short, and full activity of the arm is possible in less than three weeks.

Scapula. This bone is rarely fractured, and, if it is, the fragments are not usually displaced. The fracture may involve the spine, the glenoid, the supraspinous fossa, or the infrasupraspinous fossa. The clinical evidence of fracture may be very meager. If the fracture involves that portion of the bone not covered with much muscle, tenderness will be present and localized. Otherwise, the tenderness and pain will be diffuse, poorly localized, and perhaps mild. Immobilization in a sling or modified Velpeau dressing for three weeks is usually adequate treatment. Should there be much medial displacement of the glenoid fragment, five to eight pounds of traction in Buck's extension will reduce the fragments and maintain reduction with the arm in 90 degrees of abduction traction. If the surgical neck of the scapula is fractured, more disability will be produced. Motions of the shoulder joint in any direction will be painful. If the fracture is complete and displacement of the glenoid is present, reduction must be carried out. This is usually best accomplished by traction on the arm and manipulation. After reduction, it is usually advisable to put the patient to bed with his arm in traction in a Thomas arm splint for two or three weeks. Fixation in abduction for two or three weeks, perhaps with traction, may also be indicated in fractures through the glenoid fossa. Open operation is rarely necessary and is very difficult to perform because of overlying structures.

Dislocation of the Shoulder. This is the most common of all dislocations; it is due to transmitted violence which forces the head of the humerus out of the shallow glenoid depression of the scapula by tearing through the joint capsule.

ANTERIOR OR SUBCORACOID DISLOCATION. This is the most common type (Fig. 3) and is sustained by the patient falling on the hand or elbow with the arm abducted (6). The head of the humerus tears through the weakest spot in the capsule, i.e., at the inferior border. However, such a force more commonly results in a fracture of the head of the humerus, with which a dislocation is not infrequently confused and with which it may be associated. Clinical examination, however, usually reveals a characteristic deformity when a dislocation is present. The normal roundness of the shoulder beyond and below the tip of the acromion is lost so that the upper arm forms a straight line at a right angle with the axis of the clavicle (sometimes called deltoid flattening). The acromion is prominent. The axillary fold is depressed to a lower level. The head of the humerus can usually be palpated in its abnormal position beneath the coracoid, particularly if the arm is rotated gently. All the muscles about the joint are held rigidly. The arm is carried in mild abduction and the patient usually prefers to support the forearm with the opposite

Fig. 4. Fracture of the surgical neck of the humerus. Left, medial displacement of the shaft and some rotation of the head is noted. Closed manipulation was unsuccessful. At surgery the long head of the biceps tendon was found between the fragments. Right, end result. Six months postoperative. Reduction is excellent with good callous formation.

except that longer immobility is usually required.

Fractures of *the surgical neck* (Fig. 4) vary considerably in the type of fracture line (i.e., transverse, oblique, or serrated), and the amount of displacement of the fragments. When *complete displacement is present*, the end of the shaft fragment is often displaced upward into the axilla; the head is usually abducted and flexed and, in some instances, dislocated. The displacement of surgical neck fractures, if present, will depend on the site of the fracture and the muscles attached to the proximal fragment. The muscles which pull on the proximal fragment are the subscapularis, the supraspinatus, the infraspinatus, and the teres minor; those which pull on the distal fragment (Fig. 5) are the pectoralis major, the teres major, and the latissimus dorsi. Depending upon the activity of these muscles, the proximal fragment may be adducted or abducted in varying degrees or rotated internally or externally. It is often flexed forward as can be shown when lateral x-rays are taken. X-ray is decisive in determining the degree of deformity. The most common deformity is abduction and external rotation of the proximal fragment. The fracture is usually transverse, but may be oblique or comminuted. Disability is immediate and marked; swelling is apt to be masked by the deltoid and other shoulder muscles. Differentiation between fractures of the surgical neck of the humerus and dislocation is usually difficult to make except by x-ray because, in the acute cases, marked swelling from hematoma formation is present.

Treatment is different in the impacted type than in those with displacement. When impaction is present, treatment is limited to immobilization of the arm at the side of the trunk with a sling and swathe for 10 days to two weeks. During the following week, immobilization in a sling is sufficient, removing the arm two or three times every day for active motion; this active motion may be combined with gravity motion but not to a degree causing pain. The immobilization described above, even though moderate, may result in considerable limitation of the shoulder in the aged. Accordingly, particular attention must be paid to early active motion if the patient is elderly.

Treatment of fractures with displacement of fragments is dependent largely upon the age of the patient. In elderly patients, treat-

to recurrence; muscular strain on the extremity when the arm is abducted is one of the most frequent mechanisms. Recurrent dislocation can be prevented to a certain extent by binding the arm to the chest, but this entails *considerable inconvenience*. Operative procedures are usually necessary to correct the condition. A great many operative procedures have been recommended by various surgeons, but over the years most of them have been discarded.

The Nicola operation (7) has withstood the test of time and is a physiologic operation. The long head of the biceps tendon is cut just *proximal to its muscular attachment*, is put through a drill hole in the head of the humerus, and then resutured. The head of the humerus is kept in the glenoid cavity by the tendon which inserts into the superior margin of the glenoid.

The Roberts procedure is a modification of the Nicola operation, employing the same principle except that, instead of cutting the tendon and then threading it through the head, a piece of bone is removed; the tendon is dropped in this cavity, and the bone placed over it and sutured in place. This procedure is simpler, less time consuming, and does not entail threading the cut tendon through the drill hole in the head, which is difficult.

THE UPPER EXTREMITY

Fractures and dislocations of this part of the body will be considered under the following headings: humerus, elbow joint, forearm, and hand. In contrast to fractures of the lower extremity in which the function of weight-bearing is of primary importance, fractures of the upper extremity are of importance in relation to the finer movements, especially of the hand and wrist. Next in importance to the hand and wrist are the movements of the elbow, including pronation and supination of the forearm, whereas movements in the shoulder are the least essential. Another difference between fractures of the upper and lower extremity, *from the therapeutic standpoint*, is the importance of alignment; in the leg, good alignment is essential to satisfactory weight-bearing; but in the arm it is less necessary, although the correct carrying angle of the elbow must be maintained if the patient is to have maximum elbow *function*. *Fractures of the* upper extremity are less subject to muscle pull and the bones, being smaller than those in the lower extremity, heal more rapidly. Hence, immobilization is less prolonged, early motion more necessary and important.

Humerus. Fractures of the humerus are customarily divided into three groups: the upper end, the shaft, and the lower end (supracondylar). Their manner of occurrence is similar, i.e., they are commonly due to indirect trauma transmitted through the outstretched hand (3), although direct violence is occasionally responsible. Injuries to nerves are not infrequent in fractures of the humerus. Because of its close relation to the bone the radial nerve is most commonly involved. Brachial plexus injury is also seen.

FRACTURES AT THE UPPER END OF THE HUMERUS. Fractures at this site may be classified as those through the head and tuberosities, or those involving the surgical neck (8, 9).

Fractures *through the head* may involve one or both tuberosities. Local tenderness and pain on motion will be present, but a diagnosis can rarely be made without the x-ray, largely because deformity is absent or minimal. When the greater tuberosity is impacted into the adjacent bone (as by forced abduction), treatment is simple, requiring nothing more than a sling. When the greater *tuberosity is avulsed (as by forced contrac-*tion of the supraspinatus, infraspinatus, and teres minor muscles), treatment is more complicated because of the dislocation of the fragment. In such cases, reduction can usually be achieved by abduction and external rotation of the humerus. If reduction is not accomplished by this procedure, open reduction may be indicated. Fractures of the greater tubercle frequently occur with anterior dislocation; this occurs when the arm is forcefully abducted and externally rotated. Fractures of the *lesser tuberosity* (without involvement of adjacent bone) is uncommon; *it is due primarily to forced* pull by the subscapularis muscle. This fracture is often accompanied by a dislocation which must be reduced. Fixation of the shoulder as described elsewhere for the dislocation is usually adequate *for a fracture of the lesser tubercle,*

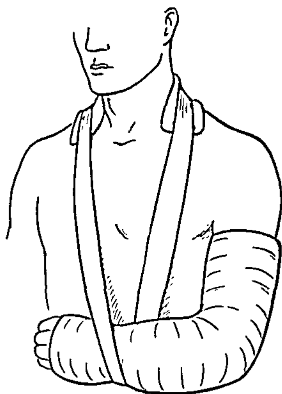

Fig. 6. Hanging cast, particularly adaptable for the ambulatory treatment of fractures of the shaft of the humerus.

elbow in about 90 degree flexion. Reduction may, of course, be indicated before the cast is applied. If the fracture is oblique, end-to-end reduction is often not possible. However, a hanging cast is still appropriate in the presence of overriding unless the fragments are separated. The cast should extend from the flexion crease of the palm up to the level of the fracture. If considerable overriding is present, the weight of the cast should be increased by making a thick cast. The cast is supported by a narrow piece of cloth or stockinet or a strip of gauze bandage. The patient must be instructed not to rest the cast on chairs, desks, and so forth, since this would destroy the traction. He must also be instructed to sleep in the sitting position. Should he lie down, the traction of the cast is lost, the fragments become displaced, and considerable pain ensues. A roentgenogram should be taken the day following application of the cast to determine position of the fragments, and repeated as indicated.

Frequently, considerable dislocation of fragments can be corrected by the hanging cast. If considerable dislocation remains after five or six days, then other methods of reduction should be undertaken—such as traction or bed rest (Fig. 7). In some cases, open reduction and internal fixation may be advisable (Fig. 8).

It must be remembered that, in the average adult, it requires eight to ten weeks to obtain a solid bony union. Immobilization of the fracture is essential until union occurs, to prevent angulation or displacement of the fragments and also to prevent pain and discomfort to the patient.

Nonunion of the humerus is more frequent than nonunion of the tibia. Bone grafting is necessary to correct this complication.

Radial nerve palsy occasionally occurs following fractures of the middle third of the humerus and, when it does, surgical exploration is indicated. Rarely is the nerve actually severed. Most of the time direct bone pressure on the nerve produces the paralysis which clears up in six to eight weeks after the pressure has been removed.

Radial nerve palsy as the result of callus overgrowth usually has an insidious onset and increases as the callus becomes larger. The callus must be removed and the nerve liberated as soon as the diagnosis is made, otherwise an irreversible paralysis occurs.

Supracondylar Fractures. This is a common injury during childhood and comprises fractures of the distal end of the humerus, nearly always transverse with displacement of the distal fragment backward and upward. Lateral displacement also occurs; only occasionally is the distal fragment displaced anteriorly. The force is nearly always transmitted to the elbow by a fall on the outstretched arm (usually with the elbow partially flexed). Examination reveals a deformity of the elbow which is apparent. The bony landmarks of the elbow are distorted, as may be best demonstrated by comparison with the uninjured side. Both olecranon and condyles are displaced posterior to the shaft of the humerus. At first glance, the deformity may appear similar to that produced by a posterior dislocation of the humerus, but examination will reveal the fact that the condyles are displaced backward with the olecranon, which does not occur in posterior dislocation. Swelling is rapid and usually intense, however, and

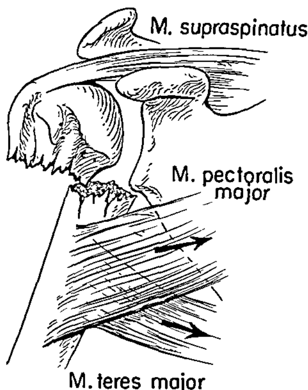

Fig. 5. Diagram of a fracture at the surgical neck of the humerus, showing a few of the various muscles which produce deformity. Most important of those pulling the upper fragment into abduction and flexion is the supraspinatus, as indicated. The teres major and pectoralis major adduct the distal fragment. Great variations exist; the position assumed by the fragments depends, in general, upon the relation of the line of fracture to the points of insertion of the various muscles.

ment as described above, without attempts at reduction, may be advisable. If the patient's physical reserve is not jeopardized by old age, reduction under anesthesia will be indicated. Reduction may be facilitated by strong downward traction on the arm while the proximal portion of the bone is pushed out with the hand in the axilla. If reduction is accomplished, its maintenance is secured by a pad in the axilla and by application of a sling with a body swathe in preference to any form of continuous traction apparatus or a cast. If reduction cannot be accomplished, operative intervention will be indicated. After reduction is achieved, immobilization may be maintained as above, perhaps utilizing the sling a week or two longer than mentioned above. Some surgeons utilize the hanging cast in such cases, but most prefer immobilization as described above.

Epiphyseal separation, while not common, is diagnosed only by the x-ray. It occurs only in children. Treatment requires accurate reduction and complete immobilization. If reduction is obtained and adduction of the arm against the chest wall does not disturb the position of the fragments, immobilization with the arm in a sling or bound against the chest with pads in the axilla is the simplest procedure if the child has minimal or no displacement. Should the child be difficult to control, then a Velpeau cast should be used for firmer immobilization. This immobilization should be maintained for four weeks or longer. Immobilization in abduction may, at times, be advisable for the first two or three weeks, particularly if it was necessary to abduct the shaft to achieve reduction.

FRACTURES OF THE SHAFT OF THE HUMERUS. Fractures of the shaft are not uncommon and occur by direct violence or by a transmitted force in falling with the arm outstretched. Transverse, oblique, spiral, and comminuted fractures occur, depending upon the degree and direction of the violence. Important is the fact that the radial nerve entwines around the shaft of the humerus at its mid-portion, thereby accounting for the frequency of radial nerve injury in this type of fracture. The deformity produced by fracture of the shaft varies and is dependent largely upon whether the break is below or above the attachment of the deltoid. If above, the upper fragment is generally pulled inward (adducted) by the pull of the pectoralis major, teres major and latissimus dorsi; if below, the deltoid generally abducts the proximal fragment. Overriding is due to the pull of all muscles acting longitudinally.

The clinical manifestations of fracture of the shaft are pronounced, the affected arm hanging uselessly, immobile, and completely disabled. The site of the fracture can often be detected by gentle palpation, preferably along the lateral aspect of the arm where the muscles are less prominent. Wrist drop, if present, is an indication of radial nerve injury. Sensory changes are rarely encountered; when present, they are very limited and inconstant in location over the dorsum of the hand.

Treatment of fractures of the humerus in the proximal third is probably most effectively carried out with a cast (10) (Fig. 6) with the

Fig. 8. Spiral fracture of upper third of humerus. Left, the sharp end of the proximal fragment was imbedded in the muscle tissue and could not be disengaged. Therefore, open reduction was indicated. Right, end result. Five months following surgery. Apposition is anatomic and function was excellent.

While traction is being maintained, the distal fragment is pushed anteriorly and molded into position. Reduction may be relatively easy, particularly in children. Immobilization is then instituted by bringing the forearm in as much acute flexion as is consistent with maintenance of a radial pulse. The flexion should never be so acute as to obliterate the pulse, because Volkmann's ischemic paralysis may rapidly follow, resulting from impaired blood supply to the forearm. If reduction has been accomplished, acute flexion is easy to maintain with very little force. If swelling is great or if the flexed position obliterates the radial pulse the *forearm must be extended until the circulation returns,* even at the expense of losing the reduction. If the patient complains of coldness, numbness, or tingling in the fingers at any time within two or three days following reduction, he should be seen immediately and, if circulatory impairment seems to exist, the dressings should be released or flexion decreased to allow adequate circulation. For this reason nothing should be placed in the fold of the elbow. If closed reduction is impossible, operation may be carried out; a simpler procedure is to insert a Kirschner wire through the olecranon for skeletal traction as recommended for intercondylar fractures or a picture-hook screw could be inserted into the olecranon and right-angle traction exerted on the elbow (Fig. 9). This has an advantage over the transverse insertion of a Kirschner wire through the olecranon because this latter procedure occasionally damages the ulnar nerve. If closed reduction is successful, fixation is achieved by a plaster splint which is molded along the posterior aspect of the arm from the axilla to the hand with the elbow in acute flexion and the forearm in supination. A bandage then holds the flexed arm to the side of the chest. Gradually increasing extension is begun in the second or third week. Seldom does any permanent disability result from this type of fracture, providing reduction has been achieved. This is explained for the most part by the fact that immobilization is carried out with flexion of the elbow and not extension. The most significant complication in adults is some permanent loss of extension. Children, as a rule, recover full elbow motion if the reduction is complete and maintained. The vascular and neural complications are ably discussed by Lipscomb and Burleson (11).

The Elbow Joint. Injuries to joints are of special significance largely because of the seriousness of damage to the articular cartilage. The nature and extent of the injury to the joint surfaces often determines the ultimate function of the joint, though it is often difficult to demonstrate clinically. The complicated structure of the elbow joint makes it

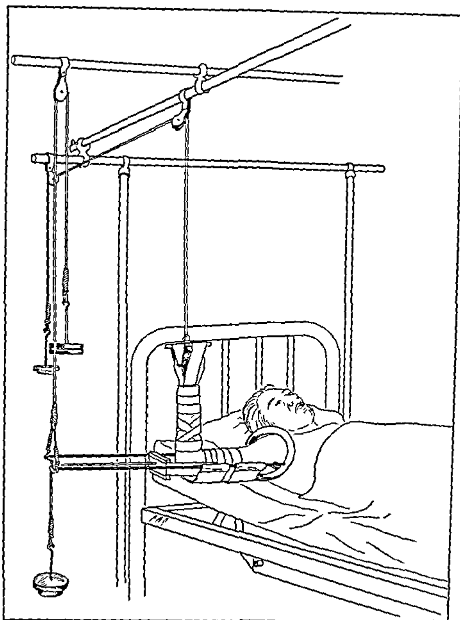

Fig. 7. Suspension and traction of the upper arm for fracture of the humerus. In this case traction is exerted by adhesive strips. When the fracture is close to the elbow, skeletal traction may be necessary; this is achieved by a wire or pin through the olecranon. Note the right angled flexion at the elbow, a position which is advantageous whenever possible because it produces less disability to the joint than that resulting from immobilization in complete extension.

tends to hide the type of deformity present. X-ray films in both views should be taken. Supracondylar fractures which involve the joint are discussed under the elbow joint.

Treatment consists of immediate reduction under complete anesthesia with fixation of acute flexion. This is performed even in the presence of severe swelling. Delay of even a few hours should be avoided. A delay of a few days is more serious because it allows the deposition of callus which will greatly interfere with subsequent replacement of the fragments and may make reduction impossible. The manipulations required depend on the position of the fragments but consist chiefly of traction. The method commonly described for reduction of supracondylar fractures is to exert traction on the forearm with the elbow extended. The authors, however, have noted that traction with the elbow flexed at a right angle is just as efficient, and apparently associated with much less trauma to the soft tissue.

Fig. 8. Spiral fracture of upper third of humerus. Left, the sharp end of the proximal fragment was imbedded in the muscle tissue and could not be disengaged. Therefore, open reduction was indicated. Right, end result. Five months following surgery. Apposition is anatomic and function was excellent.

While traction is being maintained, the distal fragment is pushed anteriorly and molded into position. Reduction may be relatively easy, particularly in children. Immobilization is then instituted by bringing the forearm in as much acute flexion as is consistent with maintenance of a radial pulse. The flexion should never be so acute as to obliterate the pulse, because Volkmann's ischemic paralysis may rapidly follow, resulting from impaired blood supply to the forearm. If reduction has been accomplished, acute flexion is easy to maintain with very little force. If swelling is great or if the flexed position obliterates the radial pulse the *forearm must be extended until the circulation returns,* even at the expense of losing the reduction. If the patient complains of coldness, numbness, or tingling in the fingers at any time within two or three days following reduction, he should be seen immediately and, if circulatory impairment seems to exist, the dressings should be released or flexion decreased to allow adequate circulation. For this reason nothing should be placed in the fold of the elbow. If closed reduction is impossible, operation may be carried out; a simpler procedure is to insert a Kirschner wire through the olecranon for skeletal traction as recommended for intercondylar fractures or a picture-hook screw could be inserted into the olecranon and right-angle traction exerted on the elbow (Fig. 9). This has an advantage over the transverse insertion of a Kirschner wire through the olecranon because this latter procedure occasionally damages the ulnar nerve. If closed reduction is successful, fixation is achieved by a plaster splint which is molded along the posterior aspect of the arm from the axilla to the hand with the elbow in acute flexion and the forearm in supination. A bandage then holds the flexed arm to the side of the chest. Gradually increasing extension is begun in the second or third week. Seldom does any permanent disability result from this type of fracture, providing reduction has been achieved. This is explained for the most part by the fact that immobilization is carried out with flexion of the elbow and not extension. The most significant complication in adults is some permanent loss of extension. Children, as a rule, recover full elbow motion if the reduction is complete and maintained. The vascular and neural complications are ably discussed by Lipscomb and Burleson (11).

The Elbow Joint. Injuries to joints are of special significance largely because of the seriousness of damage to the articular cartilage. The nature and extent of the injury to the joint surfaces often determines the ultimate function of the joint, though it is often difficult to demonstrate clinically. The complicated structure of the elbow joint makes it

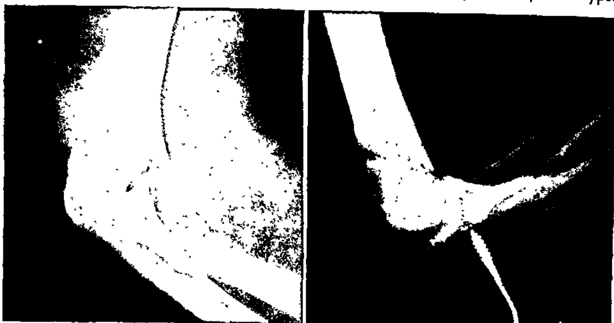

Fig. 9. Supracondylar fracture of the humerus. Left, note the superimposition of shadows which indicates overriding. Right, the reduction was obtained by skeletal traction. A picture hook screw was inserted into the olecranon and five pounds of traction applied, aided by Buck's extension. After four weeks of traction, a circular cast, axilla to hand, was applied for three more weeks before passive and active use was started.

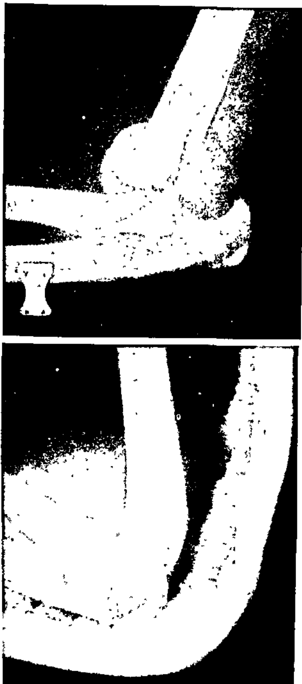
particularly prone to disability because of the possibility of bony blocks due to comminuted *fragments which resist replacement.* As mentioned elsewhere in regard to the knee, aspiration of blood from the joint cavity has great *therapeutic value.*

Intercondylar Fractures. Most injuries of the humerus involving the elbow *joint are varieties of supracondylar fractures* which, in addition to the transverse break across the humerus, also exhibit a longitudinal *fracture into the joint, thus producing two or* more distal fragments. They are called intercondylar or *Y- or T-fractures* and, since they are produced by severe violence, are occasionally comminuted. The diagnosis depends on careful x-raying. Treatment, in general, is the same as that of supracondylar fractures, as already outlined. Immediate reduction, however, is frequently impossible because of the tendency of muscle pull and upward pressure of the olecranon, which maintains separation of the fragments. Continuous traction with a wire or a screw through the olecranon with the elbow at a right angle is to be recommended. In a few instances, the fragments will have to be approximated and held together by an open operation. This is a very difficult procedure as a rule, and the amount of joint fibrosis developing in the healing process always produces a *moderate to extensive loss* of all elbow motions. In going from one method to the other, time must not be lost *because of the rapidity with which the new* bone forms and hinders further procedures. In any event, immobilization in flexion is, *with few exceptions, the position of choice* in fractures into the joint, because it tends to maintain proper position of fragments. *Perhaps of more importance is the fact* that, if ankylosis should result, this position of flexion is much less disabling than that of extension, because a *patient does not* lose the ability to shave, wash his face, and so forth. As mentioned in the preceding section, it must be remembered that immobilization of the elbow in acute flexion may produce serious circulatory disturbance distal to the fracture with the consequent development of Volkmann's contracture. The precautions previously mentioned must be heeded vigilantly in any fracture about the elbow.



A second type of elbow-joint fracture is that of the *epicondyles.* Diagnosis is made by x-ray. Treatment is simple immobilization if there is no displacement. If the epicondyle is

displaced markedly, open operation obtaining fixation of the fragment with a screw, wire, or nail may be necessary. This is particularly true of the inner epicondyle which is often forced into the elbow joint. Important is the close relation of the ulnar nerve to the inner epicondyle; during the operation, the nerve may have to be transposed in order to avoid involvement in the callus.

Fracture of the Olecranon Process. This injury may occur because of a direct blow or because of violent contraction of the powerful triceps muscle. Since the anterior surface of this bone forms part of the elbow joint, just as does the patella in the knee, a complete fracture is associated with manifestations of acute synovitis and the elbow joint becomes filled with fluid and blood. The fragments, if separated, can easily be felt through the skin. Treatment, as in the case of the patella, is best carried out through open operation that enables evacuation of the blood in the joint and accurate approximation of the fragments, which are best held in place by stainless steel wire or a long screw passed through the olecranon down the shaft of the ulna. This is the preferred method if the olecranon fragment is not comminuted. Early mobilization is feasible without the possibility of displacing the fragments; moreover, joint motion more nearly approximates the normal. Postoperatively, the elbow must be immobilized at right-angle flexion, never in extension, otherwise useful flexion of the arm is frequently lost. If the fragments are fixed securely at the time of operation, the joint can usually be immobilized with at least a few degrees of flexion without endangering the position of fragments, thereby assuring earlier return of motion in flexion. It is important to begin active motion in two or three weeks in order to prevent delayed restitution of motion in the joint, i.e., limitation of flexion.

Dislocations of the Elbow. *Complete* dislocation of the elbow without fracture is produced usually by a fall on the outstretched hand with the elbow extended and, in most instances, is of the posterior type; the coronoid process of the ulna is displaced backward over the trochlear surface of the humerus so that it (the coronoid process) lies in the olecranon fossa. The radius of necessity is also dislocated or frequently fractured (Fig. 10). The deformity is striking; the displacement of the olecranon posterior to its usual position is pronounced. The bony landmarks are disturbed, i.e., the olecranon lies far posterior to the epicondyles when compared to the uninjured side. A moderate amount of medial or lateral displacement of the forearm is usually also present. The elbow is held in semiflexion and the slightest motion of the joint produces pain. Reduction should be immediate, under general anesthesia. Any medial or lateral displacement of the olecranon must be corrected. When the olecranon is in the straight posterior position, then the forearm is brought into acute flexion by traction on the forearm and thumb pressure directly on the olecranon. An audible snap or a palpable jumping of the olecranon into place assures the surgeon that reduction has been accomplished. If acute flexion without force, and a smooth movement of flexion and extension is possible, then a confirmation x-ray should be taken. Never should the patient be permitted to come out of the anesthetic, and the reduction considered satisfactory, until x-rays show this to be true. Immobilization in a cast from the axilla to the wrist is maintained for 10 to 14 days; then motion of the wrist is encouraged. *Fracture of the coronoid process* of the ulna is sometimes an associated injury. Its presence requires fixation in more acute flexion.

Dislocation of the Head of the Radius. This injury usually occurs anteriorly and is commonly, but not always, accompanied by a fracture of the upper third of the ulna. Flexion of the elbow beyond a right angle is not possible since the head of the radius impinges against the anterior part of the humerus. The elbow is held in a semiflexed position with the hand pronated. The head of the radius can usually be seen and felt anterior to its usual position. Reduction is best achieved under anesthesia by extension of the forearm, traction, and pressure in a posterior direction against the head of the radius. The forearm should be immobilized for three weeks in a cast with the elbow flexed and the forearm supinated. Difficulty in reduction is usually caused by portions of the articular ligament being displaced into the depression normally occupied by the head or by an unreduced ulnar angulation. In these

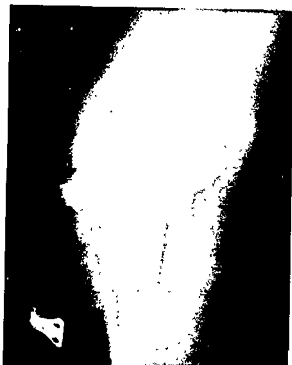


Fig. 10. Posterior dislocation of the elbow. Above left and right, in addition to the dislocation of the ulna, fragmentation and dislocation of the head of the radius is noted. Below, postreductive film. The loose fragments of the head of the radius were removed surgically to prevent loss of supination and pronation, which would result if they were left in. Fresh dislocations of the elbow are readily reduced by closed manipulation; operation is indicated only for complications such as occurred in this case.

cases, open reduction is necessary and can be accomplished only by shifting the interposing soft tissue back into its normal position. In young children, the entire head may be pulled out of its annular ligament by forceful traction of the forearm. In such instances, reduction is spontaneous or may be achieved under general anesthesia by manipulation during flexion and supination.

FRACTURE OF THE HEAD OF THE RADIUS. *The radial head really forms part of the elbow* joint moving against the capitellum of the humerus during flexion of the elbow and during supination and pronation. Fracture at this site is an important injury because of its importance in the motion of pronation and supination. Clinical manifestations include local tenderness, limitation of motion of the joint, and pain on performing these movements. An important diagnostic feature is the inability to pronate or supinate the forearm because of pain in the region of the head

of the radius. X-ray is essential to determine the degree and type of displacement which varies considerably. Mushrooming of the head with impaction of the shaft into it is a frequent deformity. In the extensive injuries, immediate operative removal of the head is advisable (12). With moderate displacement, open or, if possible, closed reduction with immobilization in flexion and supination is justifiable, particularly in growing individuals. If function remains impaired, removal of the head may be carried out later. When little or no displacement exists, treatment by immobilization without attempt at reduction may be preferable. As already mentioned, aspiration of blood in the joint will greatly hasten the reparative process and shorten disability.

The Forearm. The forearm, comprising the ulna and radius, is probably the most frequent site of fracture in the upper extremity; both bones often are involved. Forearm fractures are arbitrarily divided into fractures of the shafts of ulna and radius alone, or of both bones, and Colles' fracture. Of these, the last two are the most frequent.

FRACTURE OF THE SHAFT OF THE ULNA. This is not a frequent fracture and ordinarily presents no great problem in treatment since reduction of any displacement, if present, can readily be achieved by ordinary manipulation. Fixation in the mid-position with a cast, which immobilizes the elbow and wrist but leaves the fingers free, is maintained for five to six weeks.

The radial head is occasionally dislocated at the same time that the ulnar shaft is fractured. This is called a Monteggia fracture. It is obviously essential that this injury be detected. Reduction of the dislocation is effected first, before the ulna is manipulated, but replacement is sometimes dependent upon correction of the ulnar deformity. Open reduction is frequently necessary for the maintenance of the reduction of the dislocated head of the radius and the replacement of the ulnar fracture in anatomic reapposition.

FRACTURE OF THE SHAFT OF THE RADIUS. This is a common fracture, especially in children. (Those which involve the distal end are especially frequent and are considered separately under the heading of Colles' fracture.) Fractures of the radius are usually transverse and are most often located at the middle third or distal to it. Those in the proximal third are more rare. Displacement, if present, is usually confined to overriding or slight angulation. When the break is above the pronator teres, however, the proximal fragment is flexed and supinated, and hence markedly displaced. The treatment consists of reduction under anesthesia by manipulation and traction followed by fixation as for a fracture of the ulna. Fractures near the elbow will require sufficient flexion and supination at the joint to bring the distal fragment in line with the proximal. Fractures which resist attempts at closed reduction should be promptly operated upon and the fragments approximated under direct vision, fixed with a metal plate and screws or, in some instances intermedullary rod, and the arm immobilized.

FRACTURE OF THE SHAFTS OF BOTH ULNA AND RADIUS. The shafts of both bones of the forearm are more frequently broken than either alone, particularly in childhood. They are more difficult to manage than fractures of the radius or ulna alone, because of difficulty in achieving a good reduction of both bones (13). The force is usually direct or indirect by a fall on the outstretched palm. Considerable variation occurs in the severity of these fractures. Many are simple greenstick fractures of both bones, without displacement, but occasionally exhibiting considerable angulation. Many children sustain a complete and displaced fracture of one bone (usually the radius) with a greenstick of the other. In a considerable number both bones are broken and overriding or angulated, or both. The fracture may be compound.

Treatment consists of immediate reduction of the displacement, if present. The promptness with which reduction is carried out is almost as important in these fractures as it is in supracondylar fractures. If possible, the procedure should be instituted before swelling and muscle spasm have become pronounced, that is to say, within an hour or two after the injury. Greenstick fractures are readily reduced, although care must be taken to correct the angulation completely (Fig. 11). When overriding is present, a deep anesthesia is necessary with complete relaxation. It is particularly important in these fractures that the radius and ulna be kept from coming in con-

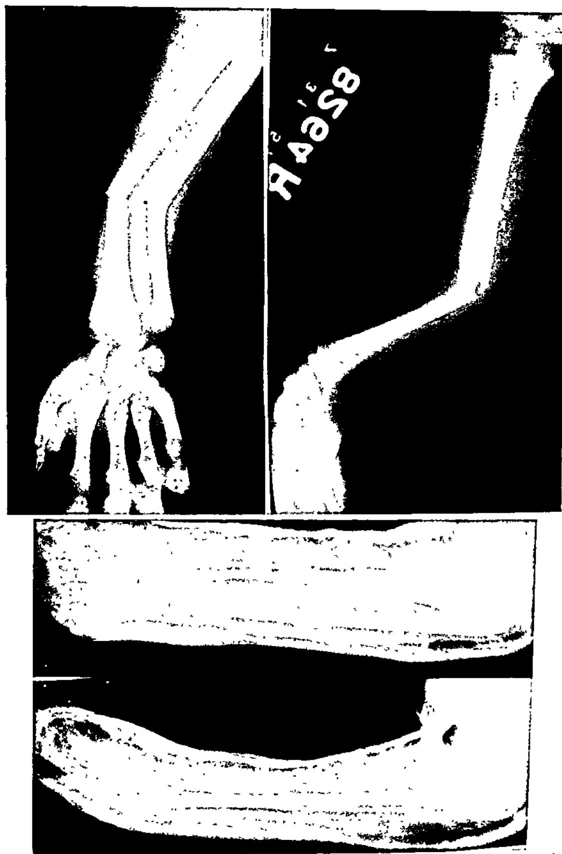

Fig. 11. Greenstick fracture of both bones of the forearm in a child, aged nine. Above, left and right, anteroposterior and lateral views reveal marked angulation deformity, but there was no false motion. Below, postreductive films showing arm in cast from knuckles to axilla. The forearm is in complete supination and right angle flexion at the elbow. The alignment of both bones is anatomic.

Fig. 12. Fracture of both bones of the forearm. A and B, anteroposterior and lateral x-rays reveal complete displacement of the bone ends associated with angulation and overriding. C and D, closed reduction of such fractures is almost impossible. A plate was used for the radius, whereas the ulnar fragments were held in place by a wire loop. Immobilization was maintained by a cast extending from the knuckles to the axilla with the elbow at right angle and the forearm in complete supination.

tact with each other across the interosseous membrane, lest a bony bridge grow across and seriously interfere with subsequent supination and pronation. This danger is revealed by appropriate x-rays which must show a clear separation between the two bones in at least one view. Reduction of these fractures is not easy. If either or both bones cannot be reduced, open reduction and internal fixation are strongly recommended (Fig. 12).

Another difficulty with fractures of both bones is preservation of reduction after it is achieved. This is due to the fact that external fixation is also a difficult matter in these injuries, particularly when the fracture is in the distal half of the forearm. The best position for immobilization is with the elbow at right angles and the forearm in supination or in semisupination (the mid-position with the palm perpendicular to the ground). The elbow and wrist must both be immobilized. The cast must be well molded and, after the plaster has set, it should be split on one side (usually the volar surface) from one end to the other to prevent any soft tissue constriction should subsequent swelling occur. Because reduction is often difficult to maintain, the site of fracture should be checked by x-ray in order to determine the position of the fragments during the first few days. The wrist is usually fixed in straight extension, but in fractures of the distal third it is often necessary to put up the forearm with the wrist in acute flexion in order to maintain the alignment and prevent volar angulation. After fixation in this abnormal position, for a week or 10 days, the forearm is then replaced in a straight splint for the remainder of the four- or five-week period.

Colles' Fracture. This is a common

fracture of the distal end of the radius and frequently involves also the styloid process of the ulna. The line of fracture is usually about 1 to 3 cm. from the articular surface. It is nearly always transverse with displacement and angulation of the distal fragment toward the dorsal surface, thus producing the well-known silver fork deformity. However, the fracture is not infrequently impacted and thus may show little or no deformity. In rare instances the distal fragment is displaced toward the palmar side, producing a reverse Colles' (Smith's) fracture. Deformity may be obscured if the patient is seen many hours after the injury because of the resulting edema and extravasation of blood. Palpation reveals the site of fracture rather accurately since the radius is superficial above the wrist; tenderness confined to the fracture site is a constant and important diagnostic sign. Point tenderness over the styloid process may also be detected. The history, moreover, is usually so characteristic as to lead to almost an immediate diagnosis in most cases. Colles' fractures are particularly common in older individuals, usually women, who fall and allow the weight of their body to be directed against the outstretched palm which is used to break the fall (Fig. 13). The impact produces forced extension and compression, transmitted to the distal end of the radius in a dorsal direction which accounts for the usual deformity. If the force is directed more in the axis of the forearm, an impacted fracture occurs. In children, the same force usually fractures the bones higher up; occasionally, however, there is an *epiphyseal separation*. The treatment of epiphyseal separation is the same as that of Colles' fracture.

Treatment is mandatory when angulation is demonstrable, even when the fracture is several weeks old. Otherwise, the patient will be unable to flex the wrist for proper function and a permanently weak, disabled, and painful hand will result (14, 15). Reduction, if performed early, is easy to effect and maintain, because of the absence of muscle pull on the distal fragment. Manipulation of a Colles' fracture should be preceded by straight traction as the least traumatic mechanism of breaking up impaction. Deep anesthesia for reduction is usually advisable but may not be necessary. Injection of novocaine into the site of fracture is often adequate. The distal fragment is molded and forced into alignment with the proximal radius, aided by strong flexion and ulnar deviation. If reduction is adequate, the hand will fall into a position equal to about 70 degrees flexion at the wrist as the forearm is raised. Immobilization is best achieved by a plaster cast but, if circular, it should always be split immediately after application to prevent damage to tissue by swelling. It need not include the elbow and should not extend down further than the metacarpophalyngeal joints. The desired position is moderate flexion with ulnar deviation. If the fracture has been reduced soon

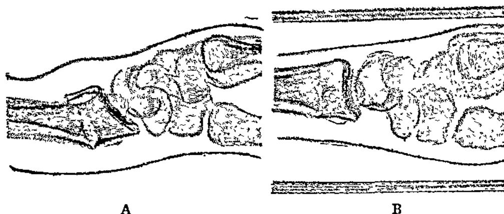

Fig. 13. Colles' fracture in an 80-year-old woman who fell on her outstretched palm. A, before reduction; note the typical silver fork deformity. There is only slight impaction in this case; B, after reduction, which was easily effected after the injection of 15 ml. of Novocain between the ends of the bone. Immobilization in an anterior and posterior splint; early motion was started on the sixth day.

after the injury and before much swelling has occurred, one must particularly watch for the danger of interference with the circulation by the cast (after edema and extravasation occur). If pain, swelling, and coldness of the fingers then develop, the cast must be split at once. Early active motion is desirable, but can rarely be started before there is some evidence of healing, lest loss of position result from the manipulation. Usually the cast can be removed in four to six weeks. Earlier removal of fixation all too frequently results in a recurrence of the original deformity, i.e., radial deviation of the wrist and posterior displacement of the distal fragment. Prolonged immobilization results in atrophy and restricted motion of the wrist. If good reduction is obtained, healing should be satisfactory and results good. Occasionally, poor results are due to injury involving the inferior radioulnar joint, a lesion which may be present in severe trauma and which requires accurate fixation.

The Hand. Under this heading will be included fractures and dislocations which involve the carpus, metacarpal bones, and phalanges. The wrist joint itself is rarely injured. The classification used will be a purely arbitrary one. It should be emphasized that all injuries of the hand are of special importance since the function of the fingers and wrist are so readily impaired. This is due to the relatively poor blood supply, the paucity of soft tissues, and the multiplicity of important structures contained in the hand (see also chapter on infections of the hand).

Fracture of the Carpal Scaphoid. A fall on the hand or a severe extension at the wrist may produce sudden pain, local tenderness, and swelling in the carpus which is often diagnosed as a sprain, but which is actually due to a fracture (Fig. 14). Any sprained wrist which has failed to heal within a reasonable length of time should be suspected of having a carpal fracture. Significant, if the scaphoid bone is fractured, is point tenderness over the bone which is best palpated on the dorsal surface in the floor of the triangle formed by the extensor and abductor tendons of the thumb (anatomic snuff box). X-ray,

Fig. 14. Fracture of the scaphoid (navicular) bone. A transverse fracture with good anatomic position is noted. Due to the poor blood supply, this bone has a high incidence of *nonunion, over 35 per cent.* Prolonged immobilization in plaster is necessary until x-ray union is visible. Frequently this may take three to five months.

however, is the only certain way of establishing the diagnosis. This is important because adequate treatment of this injury is essential if one is to avoid permanent disability (due to nonunion) which may follow an unrecognized fracture. There is rarely any displacement, merely a crack in the bone which, however, undoubtedly extends into and involves the articular space of the carpal joints. Oblique, as well as anteroposterior, and lateral x-rays may be necessary to make the diagnosis.

Treatment consists of prolonged and complete immobilization of the hand in dorsiflexion with the thumb fixed in wide abduction and the fingers flexed. This is continued for at least six weeks, even at the expense of the atrophy of disuse, since otherwise nonunion of the scaphoid bone and subsequent pain will result (16, 17). If the fragments are displaced, preliminary manipulation will be necessary. Although excision is sometimes advisable, drilling of both fragments and insertion of a bone graft into the drill holes should be tried before excision for cases of nonunion or asceptic necrosis. Good results with healing should be obtained in about 90 per cent of cases, but only if *early* recognition and early treatment are achieved; prolonged immobilization is also essential in order to avoid permanent disability.

DISLOCATION OF THE SEMILUNAR (OS LUNATUM) BONE. In forced hyperextension (dorsiflexion), the semilunar bone may be squeezed out of place and forced into the palm. The resulting deformity and local pain are usually sufficient to point to the seriousness of the injury and the x-ray easily reveals the nature of the lesion. *Treatment* consists of manual replacement of the bone under complete relaxation (general anesthesia) by hyperextension at the wrist accompanied by strong traction. Often a Thomas wrench may be required to achieve reduction. Immobilization in the mid-position for two weeks is adequate. Neglected dislocations or those impossible to reduce will necessitate open reduction or excision of the bone. The latter should be avoided, if possible.

FRACTURES OF THE METACARPAL BONES. These injuries are rather frequent but, since only a few are seriously displaced, they are rarely difficult to treat. The mode of injury is usually a direct force on the knuckles with the fist clenched. Transverse fractures, if displaced, are often merely angulated, usually toward the dorsal surface. Overriding is rare, but oblique fractures are not uncommon. Fractures accompanied by shortening can be detected by a loss of prominence of the corresponding knuckle. Deformity leads to disability and should be corrected. If angulation alone is present, it is usually in a dorsal direction and is best treated by immobilization in a dorsal splint which extends from the tips of the fingers to the mid forearm. With no displacement, a ball splint in the palm with the fingers fixed around it is adequate. When significant displacement is present, reduction is required before fixation. If manipulation is ineffective, operative reduction, perhaps with skeletal fixations, may be necessary. Usually, however, the universial splint of Allen and Mason (18) will be very appropriate (Fig. 15).

FRACTURE OF THE BASE OF THE FIRST METACARPAL BONE (BENNETT'S FRACTURE). This special type of injury (Fig. 16) is often overlooked or considered to be a sprained thumb, especially when swelling masks the deformity and diffuse pain interferes with accurate anatomic palpation. X-ray is, therefore, essential in the diagnosis. Significant displacement demands manipulation; fixation in wide abduction is essential and is best achieved with a plaster spica which embraces the wrist and thumb. Skeletal traction is usually indicated if closed reduction is not possible, the thumb being held in a position of 90 degrees of abduction. Dislocation of the proximal fragment occurs now and then and complicates therapy, which usually must be operative (19).

FRACTURES OF THE PHALANGES. Fractures without displacement are treated with simple fixation over a padded tongue depressor or, if several fingers are involved, over a ball which fixes the palm and digits in a semiflexed position; this position prevents volar angulation. If significant displacement is present, and attempts at reduction are unsuccessful, continuous traction in a modified banjo splint is used.

DISLOCATIONS IN THE HAND. In the wrist joint itself the inferior radio-ulnar joint is

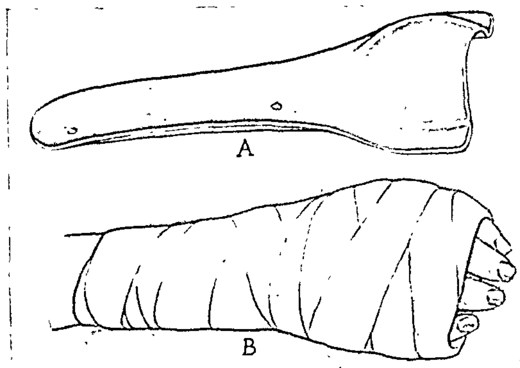

Fig. 15. *The universal hand splint* of Allen and Mason. The splint is made of aluminum and can be molded to fit the hand. It is particularly useful for fractures of the phalanges and metacarpals, maintaining the hand in a position of function.

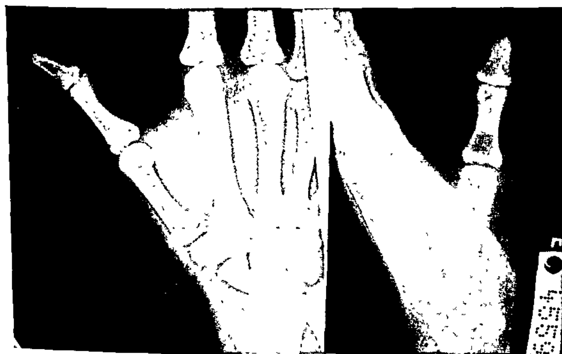

Fig. 16. Bennett fracture The fracture is located at the base of the first metacarpal. The thumb is in a position of adduction; if uncorrected, this would result in loss of ability to grasp large objects. The hand should be placed in a cast with abduction of the thumb for four to six weeks.

occasionally displaced and requires immediate reduction and immobilization; radiocarpal dislocations are even more rare and also require immediate reduction and fixation. Carpometacarpal dislocations are rare except that in the thumb the metacarpal bone may suffer a dislocation as well as a fracture. At the metacarpophalangeal joints dislocation is more common, at least in the thumb, and is due to forceful hyperextension with tearing of the anterior capsule. Reduction is not always easy and usually demands a general anesthetic; it can only be achieved by *increasing the deformity* (hyperextension) and by traction and direct pressure on the dislocated bone. Occasionally, interposition of joint capsule or of the flexor pollicis longus tendon of the thumb will prevent closed reduction and open operation must be carried out to remove the interposed tissue. Dislocation of the interphalangeal joints usually presents no great difficulty in either diagnosis or treatment. Reduction is usually easy by manipulation and traction in the line of the finger.

A special but frequent type of injury to the terminal end of the finger is mallet or baseball finger, trauma frequently being sustained by a baseball striking the end of the extended finger. The primary injury consists of rupture of the extensor tendon at or near its insertion, with a consequent subluxation deformity. Occasionally, a small chip fracture of the articular surface of the terminal phalanx is sustained. Treatment consists of immobilization with a wooden splint (tongue depressor) in hyperextension of the terminal phalanx, but function will be more completely restored by operative repair of the ruptured tendon with subsequent fixation for four to six weeks. This procedure, however, is technically difficult. The insertion of a fine Kirschner wire through the terminal and middle phalanges, then bending the wire to maintain the position of hyperextension, is probably the surest method of keeping the desired position during the healing process. Several very ingenious plastic apparatuses have recently been put on the market for keeping the terminal phalanx hyperextended and the middle interphalangeal joint flexed. Mechanically, these splints meet all the physiologic requirements for a successful outcome.

THE PELVIS

Fracture of the Pelvis. Fracture of the pelvis is usually sustained by direct impact of a crushing type from either the anteroposterior or lateral direction. Fractures through the rami of the pubis and ischium are perhaps most common (Fig. 17). Frequently, these fractures are bilateral. Another common injury is fracture through the ramus of the pubis and ischium with a fracture through the region of the sacroiliac joint on the same or opposite side. Because it is unprotected, fracture through the wing of the ilium frequently occurs. Fractures of the sacrum (usually in a transverse direction) and coccyx are important because of the tendency for such injuries to be followed by a chronic type of pain and backache, particularly in women. Although injury to the coccyx is frequently severe enough to expect a fracture, roentgenologic evidence of fracture is rare. Pain in the region of the coccyx is frequently spoken of as *coccygodynia* and may not be associated with any injury whatsoever. Because of resiliency maintained by the attachment of numerous ligaments and muscles to the pelvic ring, there is a strong tendency for fractured bones of the pelvis, even though displaced considerably at the moment of impact, to shift immediately into correct position. Obviously, if the injury is severe this spontaneous immediate reduction does not occur. As with other fractures, it is always important to search for injury to neighboring structures. Fractures of the pelvis may be accompanied by urethral, bladder, or intraabdominal injury. These associated injuries are considered separately.

Clinical Manifestation. The manifestations produced by fractures through the pelvic bones are extremely variable. When a fracture is sustained through the entire portion of the body of the *ilium* or through the region of the *sacroiliac joint* the patient is rarely able to walk. The pain in such instances is poorly localized and is described as being present over the entire side of the pelvis. If merely the *pubis* or *ischium* is fractured, walking may be possible, but will be painful. When the pubis is involved, pain and tenderness will characteristically be located in the groin. Ecchymosis will likewise appear in this region. Deformity will seldom be demonstra-

Fig. 17. Fractures of the pelvis. Arrows point to four fractures, the wing of the ileum, the acetabulum, the pubis, and the ischial tuberosity. The fracture was sustained several weeks previous to taking this x-ray.

ble except when there is a separation at the symphysis pubis, or when there is a fracture through the region of the sacroiliac joint with displacement. The amount of shock produced by fracture of the pelvis is variable, but may be considerable when the fracture extends through the supporting bones of the pelvis. Pressure on the anterior superior spines, or on the wing of each ilium simultaneously, will usually provoke pain if the pelvis is fractured.

Fracture of the *sacrum* is usually transverse and located in the lower portion. Dislocation of fragments is not frequent. Fracture of the *coccyx* is uncommon and is frequently associated with tearing of the ligaments supporting it. Diagnosis of fracture of the sacrum or coccyx is best made by x-ray, but digital examination through the rectum may be of value in revealing tenderness and extravasation of blood.

Fractures of the *acetabulum* are of two types, the most frequent being a fracture of the *rim or lip of the acetabulum* with displacement accompanying dislocation of the hip. As the head of the femur is being driven posteriorly and out of the acetabulum, the posterior lip of the acetabulum is carried with it. The *floor of the acetabulum* may be fractured and the head driven inward by a direct impact over the trochanter (such as occurs following a sideswiping automobile accident when the patient is thrown violently against the door), or by a fall with the patient landing on his feet. This type of fracture occurs chiefly in middle-aged persons, but is not common; in elderly people, the neck of the femur gives way before the floor of the acetabulum. There are few features diagnostic of this type of injury, although the patient is usually unable to walk and complains of pain upon motion of

the joint. There is no characteristic change in posture of the foot or other portion of the extremity, although slight shortening may be present.

TREATMENT. The type of treatment varies considerably, dependent upon the location of the fracture and the amount of dislocation of fragments. However, in a large percentage of patients the fracture is not complicated and no treatment other than bed rest up to six weeks in a firm bed with a fracture board under the mattress is all that is required. Attempts need not be made to reduce fractures of the rami of the pubis or ischium, even though considerable displacement of fragments exists. If there is a separation at the symphysis or a fracture through the body of the ilium with outward displacement, the pelvis should be suspended in a canvas sling, which tends to exert pressure inward from the sides. With fracture of a single ramus, bed rest for two weeks followed by weight-bearing on crutches for another four weeks is sufficient. If both rami on one side, or rami on both sides, are fractured, bed rest should be carried out for four weeks, and weight-bearing with crutches for another six weeks. Only on rare occasions is traction necessary.

If the fracture is located near the sacroiliac region and associated with much upward displacement of the pelvic fragment, reduction should be attempted. Such fractures are usually impacted so that simple traction will rarely be effective. The patient should be anesthetized and the impaction broken up (usually most effectively by forceful flexion of the thigh and adduction across the opposite hip). Heavy traction on the extremity is necessary to pull the fragments into position. This can be done readily by anesthetizing the patient on a fracture table and, with x-ray control, applying sufficient traction to reduce the fracture, then placing the patient in Buck's extension or Roger Anderson well-leg traction to maintain the desired position (Fig. 18).

Unfortunately, treatment of fractures of the *sacrum* is rather unsatisfactory without complete immobilization in bed. Adhesive splints and belts obviously do not offer much relief from the pain which may be present for many weeks unless the patient is confined to bed. Fractures of the coccyx, which are rare, are likewise benefited very little unless bed rest is obtained. Occasionally, if pain persists and is severe, removal of the coccyx may be indicated.

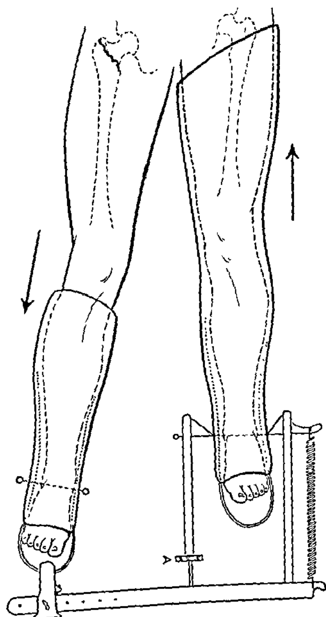

Fig. 18. The "well leg" Anderson traction (De Puy type). A steel pin is inserted through the tibia of the injured extremity and a plaster cast applied up to the knee; the yokes of one side of the splint are incorporated in the plaster. A plaster cast is applied to the uninjured extremity up to the hip, incorporating the yokes of the other side of the splint. By turning a screw pin at A, traction on the injured side is obtained by counterbalanced pressure upward on the uninjured side. Except for an occasional severe fracture of the pelvis, the use of this splint is confined chiefly to intertrochanteric fractures.

The treatment of fractures of the *acetabulum* is usually satisfactory if no displacement of the head of the femur or fragments of the acetabulum exists. Immobilization in traction in a Thomas splint for six weeks rarely fails to effect a satisfactory result. If, however, there is displacement of the fragments inward, permanent disability, including pain, may result unless the displacement is corrected. If the head of the femur is forced through the acetabulum, reduction can be achieved by traction, abduction on the upper thigh and prying the head outward; the fragments of the acetabulum usually will likewise be reduced. The insertion of an eight-inch screw with wide threads up the neck of the femur permits direct lateral skeletal traction. Usually 15 to 20 pounds of traction will reduce most central dislocations of the hip. If, in addition, 10 to 15 pounds of longitudinal traction is applied with a Buck's extension, excellent immobilization and sustained efficient traction can be obtained. Anesthesia is usually required for this reduction. Traction is maintained for at least six weeks. The patient may then be allowed up on crutches, but significant weight-bearing should not be permitted under 12 to 16 weeks. Displacement of the rim of the acetabulum may require open reduction.

Urinary Tract and Intraabdominal Injury. Tearing or puncture of urinary and intra-abdominal organs in fractures of the pelvis is surprisingly infrequent. Rupture of the bladder or urethra is the most common of these injuries and is usually produced, not by puncture, but by tearing of the structures at the moment of impact when displacement may have been considerable. Rupture of either of these two structures will be accompanied by urinary extravasation, intraperitoneal or extraperitoneal—usually the latter. The possibility of rupture of these two organs should be investigated at once. The patient is asked to void, and the urine examined for gross blood. Should the patient be unable to void, a soft rubber catheter is inserted. If a large amount of blood-stained urine is obtained, a rupture of the base of the bladder or urethra near the bladder is suggested, provided trauma to the kidney can be excluded. If only a few drops of bloody fluid are obtained by catheterization, there is a strong probability of a rupture of the bladder into the peritoneal cavity; evidence of intraperitoneal inflammation will, of course, be present. In this case, laparotomy for repair of the bladder is necessary. If the catheter cannot be inserted all the way through the urethra, and a few drops of bloody fluid are obtained, rupture of the urethra should be suspected; if present, suprapubic draining of the bladder is usually indicated to prevent serious extravasation about the urethra, scrotum, and anterior perineum. If extraperitoneal perforation at the base of the bladder exists, the application of a retention catheter usually is sufficient to prevent serious urinary extravasation. If urinary extravasation develops in spite of treatment, radical incisions may be necessary to prevent fatal infection and toxemia, although chemotherapy if started early will be of great prophylactic value (see also Ch. 41).

Any signs of peritoneal irritation in patients with fracture of the pelvis should obviously be viewed with alarm. Besides extravasation of urine from a ruptured bladder, the patient may have perforation of another viscus (particularly the intestine) or may have active severe hemorrhage. Abdominal pain, muscle rigidity, nausea, and vomiting are manifestations which should direct attention to the possibilities mentioned above. Laparotomy will obviously be indicated if perforation of the intestine, active severe hemorrhage, or intraperitoneal rupture of the bladder exists. It should be emphasized, however, that signs of peritoneal irritation may be produced by retroperitoneal hemorrhage alone, for which conservative care is indicated (see p. 812). Signs of paralytic ileus (distention and vomiting) may also be of reflex origin (see p. 826).

Sacroiliac Joint. Although strong ligaments (sacroiliac and sacrosciatic), and rough articulating surfaces allow but little motion in the sacroiliac joint, it is a true articulation since it is lined with fibrocartilage. The mechanism of production of *sacroiliac sprains* is not clear. Child-bearing, unusual strains, and the like, may be etiologic factors, but frequently there is no discernible etiologic agent. Occasionally, the disease is cured by eradication of a focus of infection, suggesting that infection may at times be important in the pathogenesis. There appears to be no doubt that occasionally there is actually a slip in the

position of the articulating surfaces so that a definite subluxation exists.

The *manifestations* are varied. The pain is usually unilateral, confined chiefly to the region of the sacroiliac joint, but may be located in the lumbosacral region or down the course of the sciatic nerve. The patient usually experiences considerable pain when stooping. Attempting to touch the floor with the hands is particularly painful. The disease may develop suddenly with severe pain and complete disability or may appear gradually with only mild symptoms. The pain may be transmitted to the abdominal wall, and if on the right side, may simulate acute appendicitis. The duration of the disease is likewise extremely variable. Tenderness over the sacroiliac joint is usually demonstrable. Muscles about the joint may be spastic.

Treatment is frequently unsatisfactory, but one of the most important factors in the treatment of the acute cases is rest in a hard bed equipped with a fracture board. This simple type of therapy, supplemented with the application of local heat and massage by a competent physical therapist is frequently followed by a cure in a week or two. Occasionally, the application of a lumbosacral canvas back support with two rigid ten-inch metal stays offers considerable support and relief when the patient is up and about. There seems to be a growing belief that at least a mild dislocation of the articulating surfaces exists, and for that reason manipulation should be performed, particularly in the stubborn cases. The exact mechanism or maneuver in this manipulation which effects relief is poorly understood, but the fact remains that manipulation is frequently followed by remarkable relief, particularly in those with no "sciatic" pain (Jostes, 1938). In the severe cases, fixation of the pelvis and extremities in a plaster cast for a few weeks should be tried. On many occasions, even in severe cases, the pain leaves as suddenly as it appears, which suggests the presence of a neurogenic factor.

Lumbosacral Sprain. Sprains in the lumbosacral region may likewise be acute or chronic. Usually, the pain comes on suddenly while the patient is performing some simple action such as stooping to the floor and lifting a very light object. People who lead a sedentary life as far as graded, routine exercise is concerned are most apt to be afflicted with the disease. Faulty posture may be of etiologic significance, and at times may be so pronounced as to allow deviation of the lumbar axis so far from the horizontal plane as to allow a slipping forward of the last lumbar vertebra on its sacral articulation. Protracted cases may be associated with congenital anomalies, involving, for example, the transverse processes or articular facets.

Pain is located in the lumbosacral region and radiates outward in all directions but rarely extends down the thigh. Occasionally, abdominal pain is present, thus adding to the diagnostic difficulty. The patient is unable to stoop over except by flexion at the hips. The spine is usually rigid throughout the entire lumbar region (poker spine). Mild tenderness is present over the lumbosacral region, but proportionally much less than the pain. During the first few days, the pain is frequently so severe that the patient is unable to get out of bed. On many occasions it is very difficult to distinguish lumbosacral sprain from a dislocated intervertebral disk (see also Ch. 24).

Treatment during the acute stage of the severe cases consists of rest in a bed fitted with a fracture board; in severe cases it may be necessary to apply a plaster cast extending from the mid-thoracic region down to the femoral trochanters. If recovery is slow, the cast may be substituted for a stiff supportive jacket. The daily application of heat, by a bake or otherwise, adds much to the patient's comfort and no doubt facilitates healing. The patient may have to wear a lumbosacral support of some kind for many weeks or even months. He should be instructed not to lift heavy objects until he is completely well. If pain and disability become prolonged, such operative procedures as spinal fusion may be indicated. In all of these cases the possibility of a dislocated intervertebral disk (nucleus pulposus) must be kept in mind as a cause of symptoms. Many patients with low back pain are markedly improved or even cured by manipulation; the explanation of relief by manipulation is not clear since not all patients relieved have actual dislocation of bony structure.

THE LOWER EXTREMITY

There are numerous features about fractures of the lower extremity which are peculiar to fractures in this location; these features must be constantly borne in mind if good results are to be obtained (20). For example, the bones which are associated with weight-bearing must obviously be immobilized longer than other bones. Furthermore, it is particularly important that correct alignment with proper position of fragments be obtained and maintained, because alignment vitally affects the function of weight-bearing; subsequent pain and disability are apt to be severe if position and alignment are not good, chiefly because of disturbances in the line of weight-bearing. In the anteroposterior plane, the line of weight-bearing should pass from the anterior superior spine and cross the patella extending downward to the interdigital space between the large and second toe. In the lateral plane, the weight-bearing line should pass from the great trochanter downward through the head of the fibula and external malleolus (Fig. 19).

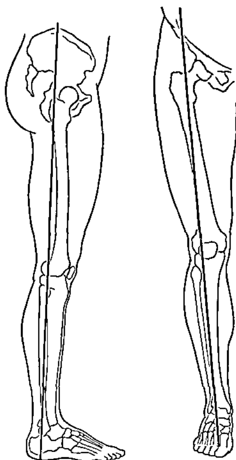

Fig. 19. Lines drawn through the bones of the lower extremity showing the optimum axis of weight-bearing.

Neck of the Femur. Fractures through the neck of the femur are to be considered serious, not only because of their frequency and high initial mortality (up to 25 per cent) but particularly because of the high incidence of nonunion. A high incidence of 30 to 40 per cent nonunion often followed the old closed reduction methods. Nonunion has been considerably reduced by the introduction in recent years of methods of internal fixation, as will be described later. Fractures of the neck of the femur are intracapsular, i.e., medial to the attachment of the capsule of the hip joint. Dislocation of fragments is variable. The explanation for the frequency of nonunion in fractures of the hip lies in the fact that the blood supply of the head of the femur is seriously impaired by fracture of the neck, particularly when the break is intracapsular, because the ligamentum teres is then the sole source of nourishment; in many instances, the head of the femur receives no blood supply whatever through the ligamentum teres (Fig. 20). Because of the more profuse though still meager blood supply furnished by the joint capsule, union is much more apt to occur if the fracture is distal to this point, i.e., extracapsular. The outlook as to union of fragments is much more favorable if impaction is present.

Fractures of the hip are most common after the age of fifty and are particularly prone to occur in women. A variable amount of shock may be produced in these patients, even though the fracture may be sustained with no more injury than a fall to the ground from a standing position and presumably occurs in most instances by direct impact on the great trochanter. In many instances, the fracture is the cause of the fall and not the result, particularly in the aged. Decalcification and other organic changes incident to old age may make the bone so weak and brittle that a sudden twist or strain on the hip may result in fracture at the weak point, namely, the neck of the femur.

position of the articulating surfaces so that a definite subluxation exists.

The *manifestations* are varied. The pain is usually unilateral, confined chiefly to the region of the sacroiliac joint, but may be located in the lumbosacral region or down the course of the sciatic nerve. The patient usually experiences considerable pain when stooping. *Attempting to touch the floor with* the hands is particularly painful. The disease may develop suddenly with severe pain and complete disability or may appear gradually with only mild symptoms. The pain may be transmitted to the abdominal wall, and if on the right side, may simulate acute appendicitis. The duration of the disease is likewise extremely variable. Tenderness over the sacroiliac joint is usually demonstrable. Muscles about the joint may be spastic.

Treatment is frequently unsatisfactory, but one of the most important factors in the treatment of the acute cases is rest in a hard bed equipped with a fracture board. This simple type of therapy, supplemented with the application of local heat and massage by a competent physical therapist is frequently followed by a cure in a week or two. Occasionally, the application of a lumbosacral canvas back support with two rigid ten-inch metal stays offers considerable support and relief when the patient is up and about. There seems to be a growing belief that at least a mild dislocation of the articulating surfaces exists, and for that reason manipulation should be performed, particularly in the stubborn cases. The exact mechanism or maneuver in this manipulation which effects relief is poorly understood, but the fact remains that manipulation is frequently followed by remarkable relief, particularly in those with no "sciatic" pain (Jostes, 1938). In the severe cases, fixation of the pelvis and extremities in a plaster cast for a few weeks should be tried. On many occasions, even in severe cases, the pain leaves as suddenly as it appears, which suggests the presence of a neurogenic factor.

Lumbosacral Sprain. Sprains in the lumbosacral region may likewise be acute or chronic. Usually, the pain comes on suddenly while the patient is performing some simple action such as stooping to the floor and lifting a very light object. People who lead a sedentary life as far as graded, routine exercise is concerned are most apt to be afflicted with the disease. Faulty posture may be of etiologic significance, and at times may be so pronounced as to allow deviation of the lumbar axis so far from the horizontal plane as to allow a slipping forward of the last lumbar vertebra on its sacral articulation. Protracted cases may be associated with congenital anomalies, involving, for example, the transverse processes or articular facets.

Pain is located in the lumbosacral region and radiates outward in all directions but rarely extends down the thigh. Occasionally, abdominal pain is present, thus adding to the diagnostic difficulty. The patient is unable to stoop over except by flexion at the hips. The spine is usually rigid throughout the entire lumbar region (poker spine). Mild tenderness is present over the lumbosacral region, but proportionally much less than the pain. During the first few days, the pain is frequently so severe that the patient is unable to get out of bed. On many occasions it is very difficult to distinguish lumbosacral sprain from a dislocated intervertebral disk (see also Ch. 24).

Treatment during the acute stage of the severe cases consists of rest in a bed fitted with a fracture board; in severe cases it may be necessary to apply a plaster cast extending from the mid-thoracic region down to the femoral trochanters. If recovery is slow, the cast may be substituted for a stiff supportive jacket. The daily application of heat, by a bake or otherwise, adds much to the patient's comfort and no doubt facilitates healing. The patient may have to wear a lumbosacral support of some kind for many weeks or even months. He should be instructed not to lift heavy objects until he is completely well. If pain and disability become prolonged, such operative procedures as spinal fusion may be indicated. In all of these cases the possibility of a dislocated intervertebral disk (nucleus pulposus) must be kept in mind as a cause of symptoms. Many patients with low back pain are markedly improved or even cured by manipulation; the explanation of relief by manipulation is not clear since not all patients relieved have actual dislocation of bony structure.

THE LOWER EXTREMITY

There are numerous features about fractures of the lower extremity which are peculiar to fractures in this location; these features must be constantly borne in mind if good results are to be obtained (20). For example, the bones which are associated with weight-bearing must obviously be immobilized longer than other bones. Furthermore, it is particularly important that correct alignment with proper position of fragments be obtained and maintained, because alignment vitally affects the function of weight-bearing; subsequent pain and disability are apt to be severe if position and alignment are not good, chiefly because of disturbances in the line of weight-bearing. In the anteroposterior plane, the line of weight-bearing should pass from the anterior superior spine and cross the patella extending downward to the interdigital space between the large and second toe. In the lateral plane, the weight-bearing line should pass from the great trochanter downward through the head of the fibula and external malleolus (Fig. 19).

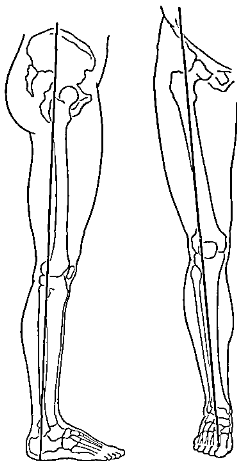

Fig. 19. Lines drawn through the bones of the lower extremity showing the optimum axis of weight-bearing.

Neck of the Femur. Fractures through the neck of the femur are to be considered serious, not only because of their frequency and high initial mortality (up to 25 per cent) but particularly because of the high incidence of nonunion. A high incidence of 30 to 40 per cent nonunion often followed the old closed reduction methods. Nonunion has been considerably reduced by the introduction in recent years of methods of internal fixation, as will be described later. Fractures of the neck of the femur are intracapsular, i.e., medial to the attachment of the capsule of the hip joint. Dislocation of fragments is variable. The explanation for the frequency of nonunion in fractures of the hip lies in the fact that the blood supply of the head of the femur is seriously impaired by fracture of the neck, particularly when the break is intracapsular, because the ligamentum teres is then the sole source of nourishment; in many instances, the head of the femur receives no blood supply whatever through the ligamentum teres (Fig. 20). Because of the more profuse though still meager blood supply furnished by the joint capsule, union is much more apt to occur if the fracture is distal to this point, i.e., extracapsular. The outlook as to union of fragments is much more favorable if impaction is present.

Fractures of the hip are most common after the age of fifty and are particularly prone to occur in women. A variable amount of shock may be produced in these patients, even though the fracture may be sustained with no more injury than a fall to the ground from a standing position and presumably occurs in most instances by direct impact on the great trochanter. In many instances, the fracture is the cause of the fall and not the result, particularly in the aged. Decalcification and other organic changes incident to old age may make the bone so weak and brittle that a sudden twist or strain on the hip may result in fracture at the weak point, namely, the neck of the femur.

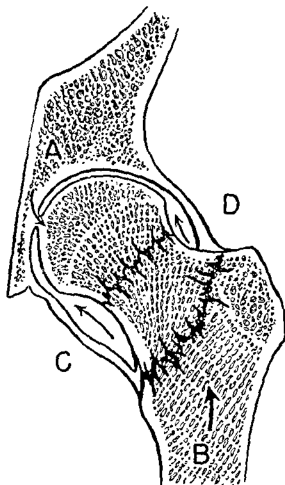

Fig 20. The role of blood supply in healing of fractures. Although an intracapsular fracture rarely occurs simultaneously with an extracapsular fracture as shown in the illustration, they are illustrated together to show the difference in blood supply at the two levels. The blood supply of the proximal fragment at the level of the intracapsular fracture is very meager, consisting only of the inadequate supply coming through the ligamentum teres, thus accounting for the high incidence of nonunion with this type. When the facture is extracapsular, the medullary blood supply (B) is very abundant and the capsular blood supply (C and D) is of value in maintaining adequate blood supply in the proximal fragment to allow healing.

CLINICAL MANIFESTATIONS. Invariably the patient is unable to walk, except in the occasional instance when the fragment is solidly impacted. In the absence of impaction, a rather typical deformity is usually present. The leg is externally rotated, the thigh slightly abducted, and the knee flexed not more than a few degrees if at all. Comparative measurements of the extremities from the anterior superior spine to the internal malleolus will reveal a shortening up to a few centimeters on the injured side. The base of Bryant's triangle will be shortened over that of the normal side and the trochanter will be above Nélaton's line (Fig. 21). There will, of course, be no shortening in the measurement from the great trochanter to the external malleolus. To avoid error, all measurements involving comparison of the two extremities must be made with the uninjured extremity in the same position as the injured. It must be remembered that the results of the measurements just mentioned may be the same in a dislocation of the hip as they are in fractures of the neck of the femur, but in dislocations the knee remains in considerable flexion which cannot be overcome by force. The amount of pain will be variable, but frequently is trivial; it will naturally be increased markedly upon motion. Tenderness is diffuse over the region of the hip. Rotation of the thigh will reveal the fact that the trochanter turns in the palm of the hand instead of rotating in a large arc, as is the case when the neck is intact. Such maneuvers as traction on the extremity or pressure upward on the heel will reveal changes in the measurement between the anterior and superior spine and internal malleolus. However, these maneuvers usually produce so much pain as to be justifiable only in patients with nonunion. If the fracture is impacted, there may be only minimal deformity or deviation in measurements from the normal side. However, fracture with impaction is often associated with a valgus deformity. If examination is painful, it should be omitted and an x-ray taken, thereby enabling one to discern the exact extent of injury. An x-ray is particularly indicated in injuries about the hip, especially in elderly people, since disability and other evidences of fracture may be slight if impaction is present; moreover, the clinical diagnosis may be inaccurate when an impacted fracture is present.

TREATMENT. In many instances, *emergency treatment* can be instituted before arrival at the hospital. The most important feature in emergency therapy is fixation of the extremity, thereby preventing movement of the fractured ends upon each other which is painful and contributes to shock. One of the best agents available for obtaining fixation in these emergency situations is the Thomas (full-ring) or Keller (half-ring) splint. If one

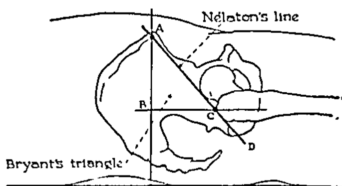

Fig. 21. Bryant's triangle and Nélaton's line. The triangle is drawn (with the patient lying supine) by dropping a perpendicular from the anterior superior spine, and carrying a second line BC, from the greater trochanter, perpendicular to this line. A third line, AC, connects the spine and trochanter. If the line BC is shortened over such a line drawn on the opposite side, an upward displacement of the trochanter, such as would be produced by a dislocation or fracture of the neck of the femur, is indicated. Nélaton's line AD extends from the anterior superior spine to the ischeal tuberosity, and normally should pass through the tip of the greater trochanter. If the greater trochanter lies above this line a dislocation or fracture of the neck of the femur probably exists.

of these is not available, a Liston board splint extending from beyond the foot to the axilla should be applied. A hypodermic of morphine will be effective in eliminating pain and minimizing the development of shock. The splint should be left on during transportation of the patient to the hospital and even while the initial x-ray is being taken. If the patient is in shock, treatment of the fracture should be postponed until the shock is relieved.

The closed method of treatment with a plaster cast has been supplanted entirely in recent years by operative fixation of fragments (Fig. 22) by means of some type of nail or pin (21, 22, 23). This method has the great advantage of requiring no external fixation;

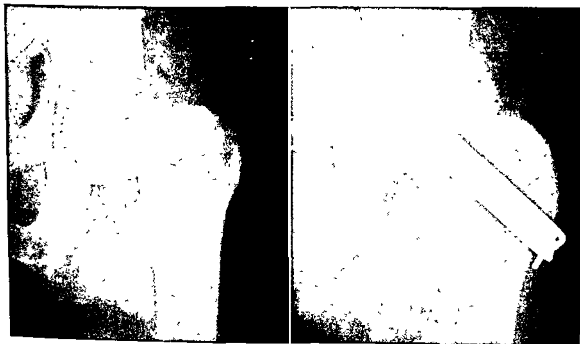

Fig. 22. Fracture of the neck of the femur. Left, three major deformities consisting of coxa vara, shortening, and external rotation of the leg are present. Right, postoperative films. After insertion of a pin, all deformity has been corrected.

it shortens the period of bed rest, allowing weight-bearing much earlier. These two factors are very desirable not only from the standpoint of the patient's health and comfort but are also very conducive to healing of the fracture. In the hands of well-qualified surgeons, the incidence of solid bony union with no complications is about 85 per cent. Early complications are infection, inadequate reduction, and "incorrect pinning." Late complications are "backing out" of the pin, with loss of adequate fixation, and aseptic necrosis of the head.

Several methods of inserting these pins or nails have been described. Regardless of which method is used, reduction must first be obtained. In order to first achieve good reduction, manipulation is carried out, under a local or general anesthetic, by the Leadbetter (24) maneuver, which is an excellent method of correcting the displacement. This maneuver consists of manipulation with the hip and knee flexed and the pelvis fixed; while the leg is in this position, traction is exerted upward on the thigh which is gently rotated internally to engage the fragments. When the reduction is effected, the hip is brought out into extreme abduction with the foot and leg in internal rotation, fixation of the pelvis being maintained by abduction of the other thigh. An efficient reduction is indicated if the heel of the affected leg will remain in the palm of the surgeon in an abducted and internally rotated position (heel-palm test).

One method of internal fixation consists of making an incision one or two inches long over the trochanter, and inserting two or three heavy wires through the trochanter into the head of the femur by means of a drill. A Smith-Petersen nail of proper length is threaded over the wire, which is shown by x-ray to be in the best position, and driven through the trochanter into the head to obtain complete fixation. Some surgeons prefer to drive the nail without the aid of the guide wire, particularly if a protractor is used to guide the direction of the nail. Regardless of the method of nailing used, the x-ray will be of inestimable value in determining whether or not the position is satisfactory. A lateral as well as an anteroposterior x-ray is necessary. These x-rays should be made, developed, and read after reduction and before incision has been made. They should be repeated and read after the internal fixation material is in place and before the wound is closed. After closure of the wound the patient is placed in bed with the affected leg suspended with the aid of a few pounds of traction for about four weeks, after which time he may be allowed up, using crutches for a period of four to six months, permitting only slight weight-bearing at first. The nail need not be removed unless complications develop.

Instead of using a large nail as a means of internal fixation, more recent procedures have employed four smaller pins (Moore) threaded at the end, which engage the head of the femur. Ordinarily, the x-ray will be of value in determining whether or not union is taking place insofar as decalcification with decrease in density takes place in the head of the femur under normal circumstances of healing.

Another modification of internal fixation, using an originally designed incision and flange as reported by Cubbins, Callahan, and Scuderi (25) is very satisfactory. Even though the incision appears extensive, incising the capsule and allowing full view of the fracture line, they report only one death in 105 patients operated upon; union was obtained in 90 per cent of the fresh fractures. The incision has an important advantage insofar as pieces of periosteal synovial membrane, which might lodge between the bone fragments and encourage nonunion, can be seen and removed. The incision has an added advantage in that the extent of reduction by the Leadbetter maneuver can be observed.

If the x-ray shows signs of necrosis of the head, or erosion of the neck of the femur, protection by means of the caliper splint will have to be extended and weight-bearing postponed for several months. The insertion of bone grafts into the area of aseptic necrosis aids in the revascularization of the area, and many aseptic necrotic heads can be salvaged. This is especially important and should be recommended in the younger group of patients (i.e., 60 years of age or younger). Phemister has discussed the features of aseptic bone necrosis in detail. X-ray changes, including increased density of the head, may be the first evidence of necrosis.

As already mentioned, *nonunion* in frac-

tures of the neck of the femur occurs frequently, even when treated in expert hands, although the incidence has been reduced sharply by internal fixation. However, a positive diagnosis of nonunion cannot be made earlier than six months after the injury, even with the aid of the x-ray. Nonunion is suggested in the x-ray by an absorption of bone at the line of fracture, but particularly by a more dense appearance of the head of the femur, or at the fracture line. This apparently paradoxical condition (viz., increased density of the head of the femur associated with nonunion) is due to the fact that normal bones with adequate blood supply always exhibit decalcification following immobilization. The absence of the absorption of calcium, therefore, is indicative of inadequate or absent blood supply.

Five major operative procedures are available in the treatment of nonunion of fracture of the neck of the femur.

1. Internal fixation, using nails or pins as described for the treatment of fresh fractures, may be successful, but obviously in a lower percentage of cases.

2. A bone graft may be inserted through the trochanter into the head, a procedure more difficult than nailing, but perhaps associated with a higher percentage of success.

3. The Brackett operation may be very successful if the head is viable. The operation consists of excavating the central portion of the head of the femur and inserting the fashioned end of the shaft. The trochanter must be cut off and transplanted lower down to avoid interference in motion. Weight-bearing is permitted in eight weeks.

4. The Whitman operation, consisting of removal of the head and insertion of the fashioned end of the shaft into the acetabulum with transplantation of the trochanter and its attached muscles as in the Brackett operation, may be very adaptable, particularly when any of the other procedures for nonunion have resulted in failure. This operation always leaves the patient with a bad limp and a moderately painful hip and should only be used if at least 1.5 inches of the neck is available to be rounded off and placed in the acetabulum.

5. Osteotomy (cutting through the entire thickness of the shaft), either high or low, may be performed to eliminate shearing action at the fracture and to bring the line of weight-bearing at a right angle to the fracture surfaces. This operation is less extensive and shocking than the reconstruction procedures and may be employed in patients who would not stand more extensive operations.

6. The substitution stem prosthesis has become very popular, and the results have been most gratifying. Excellent end results up to five years have been reported. No one knows how long these hips will continue to function satisfactorily. Some men are advocating this in all fresh fractures of the neck of the femur in the older age group (75 and above) because the postoperative convalescence is short and ambulation early, usually four to six weeks after operation.

The choice of the six procedures will depend largely upon the features of the case under consideration. It must be remembered that some of them are quite formidable procedures and will not be tolerated by patients who are poor risks, particularly the aged. Moreover, the fixation incident to fibrous union not infrequently will eliminate most of the pain and disability of nonunion, and will contraindicate any operative procedures, particularly in the aged.

Dislocation of the Hip. Dislocations of the hip are relatively uncommon and are of two types; namely, posterior and anterior (Fig. 23). By far the majority are of the former type. Occasionally they are complicated by fractures of the acetabulum, consisting usually of merely the rim of the acetabulum (see p. 491).

A complication of dislocation of the hip only recently appreciated lies in the possibility of aseptic necrosis of the head of the femur (Phemister, 1934), a phenomenon which occurs, however, more commonly in fracture of the neck of the femur.

Posterior Dislocation. The mechanism producing this type of injury usually consists of an upward thrust on the knee with the thigh flexed, adducted, and rotated internally. The head of the femur is forced through the posterior capsule and lies on the ilium posterior to and above the acetabulum. The deformity, consisting of internal rotation and adduction of the extremity with mild flexion of the thigh, is quite characteristic. There is a short-

it shortens the period of bed rest, allowing weight-bearing much earlier. These two factors are very desirable not only from the standpoint of the patient's health and comfort but are also very conducive to healing of the fracture. In the hands of well-qualified surgeons, the incidence of solid bony union with no complications is about 85 per cent. Early complications are infection, inadequate reduction, and "incorrect pinning." Late complications are "backing out" of the pin, with loss of adequate fixation, and aseptic necrosis of the head.

Several methods of inserting these pins or nails have been described. Regardless of which method is used, reduction must first be obtained. In order to first achieve good reduction, manipulation is carried out, under a local or general anesthetic, by the Leadbetter (24) maneuver, which is an excellent method of correcting the displacement. This maneuver consists of manipulation with the hip and knee flexed and the pelvis fixed; while the leg is in this position, traction is exerted upward on the thigh which is gently rotated internally to engage the fragments. When the reduction is effected, the hip is brought out into extreme abduction with the foot and leg in internal rotation, fixation of the pelvis being maintained by abduction of the other thigh. An efficient reduction is indicated if the heel of the affected leg will remain in the palm of the surgeon in an abducted and internally rotated position (heel-palm test).

One method of internal fixation consists of making an incision one or two inches long over the trochanter, and inserting two or three heavy wires through the trochanter into the head of the femur by means of a drill. A Smith-Petersen nail of proper length is threaded over the wire, which is shown by x-ray to be in the best position, and driven through the trochanter into the head to obtain complete fixation. Some surgeons prefer to drive the nail without the aid of the guide wire, particularly if a protractor is used to guide the direction of the nail. Regardless of the method of nailing used, the x-ray will be of inestimable value in determining whether or not the position is satisfactory. A lateral as well as an anteroposterior x-ray is necessary. These x-rays should be made, developed, and read after reduction and before incision has been made. They should be repeated and read after the internal fixation material is in place and before the wound is closed. After closure of the wound the patient is placed in bed with the affected leg suspended with the aid of a few pounds of traction for about four weeks, after which time he may be allowed up, using crutches for a period of four to six months, permitting only slight weight-bearing at first. The nail need not be removed unless complications develop.

Instead of using a large nail as a means of internal fixation, more recent procedures have employed four smaller pins (Moore) threaded at the end, which engage the head of the femur. Ordinarily, the x-ray will be of value in determining whether or not union is taking place insofar as decalcification with decrease in density takes place in the head of the femur under normal circumstances of healing.

Another modification of internal fixation, using an originally designed incision and flange as reported by Cubbins, Callahan, and Scuderi (25) is very satisfactory. Even though the incision appears extensive, incising the capsule and allowing full view of the fracture line, they report only one death in 105 patients operated upon; union was obtained in 90 per cent of the fresh fractures. The incision has an important advantage insofar as pieces of periosteal synovial membrane, which might lodge between the bone fragments and encourage nonunion, can be seen and removed. The incision has an added advantage in that the extent of reduction by the Leadbetter maneuver can be observed.

If the x-ray shows signs of necrosis of the head, or erosion of the neck of the femur, protection by means of the caliper splint will have to be extended and weight-bearing postponed for several months. The insertion of bone grafts into the area of aseptic necrosis aids in the revascularization of the area, and many aseptic necrotic heads can be salvaged. This is especially important and should be recommended in the younger group of patients (i.e., 60 years of age or younger). Phemister has discussed the features of aseptic bone necrosis in detail. X-ray changes, including increased density of the head, may be the first evidence of necrosis.

As already mentioned, *nonunion* in frac-

tures of the neck of the femur occurs frequently, even when treated in expert hands, although the incidence has been reduced sharply by internal fixation. However, a positive diagnosis of nonunion cannot be made earlier than six months after the injury, even with the aid of the x-ray. Nonunion is suggested in the x-ray by an absorption of bone at the line of fracture, but particularly by a more dense appearance of the head of the femur, or at the fracture line. This apparently paradoxical condition (viz., increased density of the head of the femur associated with nonunion) is due to the fact that normal bones with adequate blood supply always exhibit decalcification following immobilization. The absence of the absorption of calcium, therefore, is indicative of inadequate or absent blood supply.

Five major operative procedures are available in the treatment of nonunion of fracture of the neck of the femur.

1. Internal fixation, using nails or pins as described for the treatment of fresh fractures, may be successful, but obviously in a lower percentage of cases.

2. A bone graft may be inserted through the trochanter into the head, a procedure more difficult than nailing, but perhaps associated with a higher percentage of success.

3. The Brackett operation may be very successful if the head is viable. The operation consists of excavating the central portion of the head of the femur and inserting the fashioned end of the shaft. The trochanter must be cut off and transplanted lower down to avoid interference in motion. Weight-bearing is permitted in eight weeks.

4. The Whitman operation, consisting of removal of the head and insertion of the fashioned end of the shaft into the acetabulum with transplantation of the trochanter and its attached muscles as in the Brackett operation, may be very adaptable, particularly when any of the other procedures for nonunion have resulted in failure. This operation always leaves the patient with a bad limp and a moderately painful hip and should only be used if at least 1.5 inches of the neck is available to be rounded off and placed in the acetabulum.

5. Osteotomy (cutting through the entire thickness of the shaft), either high or low, may be performed to eliminate shearing action at the fracture and to bring the line of weight-bearing at a right angle to the fracture surfaces. This operation is less extensive and shocking than the reconstruction procedures and may be employed in patients who would not stand more extensive operations.

6. The substitution stem prosthesis has become very popular, and the results have been most gratifying. Excellent end results up to five years have been reported. No one knows how long these hips will continue to function satisfactorily. Some men are advocating this in all fresh fractures of the neck of the femur in the older age group (75 and above) because the postoperative convalescence is short and ambulation early, usually four to six weeks after operation.

The choice of the six procedures will depend largely upon the features of the case under consideration. It must be remembered that some of them are quite formidable procedures and will not be tolerated by patients who are poor risks, particularly the aged. Moreover, the fixation incident to fibrous union not infrequently will eliminate most of the pain and disability of nonunion, and will contraindicate any operative procedures, particularly in the aged.

Dislocation of the Hip. Dislocations of the hip are relatively uncommon and are of two types; namely, posterior and anterior (Fig. 23). By far the majority are of the former type. Occasionally they are complicated by fractures of the acetabulum, consisting usually of merely the rim of the acetabulum (see p. 491).

A complication of dislocation of the hip only recently appreciated lies in the possibility of aseptic necrosis of the head of the femur (Phemister, 1934), a phenomenon which occurs, however, more commonly in fracture of the neck of the femur.

Posterior Dislocation. The mechanism producing this type of injury usually consists of an upward thrust on the knee with the thigh flexed, adducted, and rotated internally. The head of the femur is forced through the posterior capsule and lies on the ilium posterior to and above the acetabulum. The deformity, consisting of internal rotation and adduction of the extremity with mild flexion of the thigh, is quite characteristic. There is a short-

Fig. 23. Dislocation of the hip. A, roentgenogram shows an anterior dislocation, with the head of the femur lying in the obturator foramen. The dotted line illustrates the usual position of the head in posterior dislocation of the hip which is more frequent than the anterior type; B, x-ray film after reduction.

ening of the distance between the anterior superior spine and the internal malleolus compared with the uninjured side. The amount of pain produced by the injury is variable, but frequently is surprisingly mild. On many occasions, however, the amount of pain, tenderness, and local findings is so similar to the manifestations encountered in fracture of the hip that a differential diagnosis cannot be made without the aid of an x-ray.

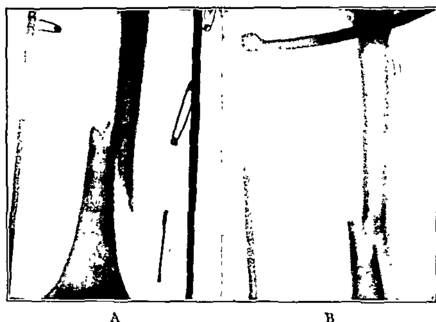
Reduction may be performed in several ways. The Bigelow manipulation as herein described is one of the effective procedures. A general anesthesia should be administered to obtain good relaxation; cyclopropane or intravenous pentothal are satisfactory. The thigh is flexed, adducted, and rotated internally while traction is being made by the operator's arm hooked under the patient's bent knee. This procedure should disengage the head of the femur. The thigh is then abducted, and increased traction made upon the extremity while it is being rotated externally for a posterior dislocation, and internally for an anterior dislocation. Completion of this maneuver usually results in reduction, but if this procedure is ineffective it should be repeated. Opinions differ as to the length of time

that should elapse before weight-bearing is allowed, but walking before 12 or 16 weeks is considered inadvisable by most surgeons. As intimated previously, the greatest danger from the standpoint of complications in convalescent care lies in the possibility of aseptic necrosis of the head of the femur resulting from destruction of the blood supply through the round ligament. Therefore, too early and extensive weight-bearing may give rise to collapse of the head with subsequent permanent lameness (Phemister). The x-ray may be helpful in determining the development of necrosis as noted by increased density, but would rarely be noted under two or three months.

Anterior Dislocation. Injury of this type, with dislocation of the head of the femur through the anterior or lower portion of the capsule so that it rests anteriorly upon the obturator foramen, is usually produced by violent abduction of the hip. The deformity produced is much different than that observed in posterior dislocation. The thigh is abducted and flexed with external rotation. The knee is also flexed. The extremity cannot be extended or adducted while the dislocation exists. Reduction is performed by flexing and abducting the thigh (after administration of an anesthetic) and the use of traction on the extremity. The thigh is then rotated inward and extended. Reduction may be faciliated by having an assistant exert pressure laterally against the proximal part of the thigh.

The Stimson method is not as well known as the Bigelow maneuver but by many is considered easier to perform and less traumatizing to the patient. The patient is anesthetized face down and the dislocated hip is permitted to hang over the side of the cart or operating table. The thigh is flexed to right angle with the spine and the knee at right angle to the thigh. Gentle downward pull is then exerted on the leg, putting maximum pressure in the popliteal area. For a posterior dislocation, the leg is slowly rotated clockwise; for an anterior dislocation, it is rotated counterclockwise. The head can be felt as it rides over the rim of the acetabulum, and a definite "pop" can be felt and heard when the reduction occurs.

The Trochanters. Intertrochanteric fractures are sustained in a manner similar to fractures of the hip, but occur in older people, and are probably associated with more violence and trauma. Although extracapsular fractures rarely lead to nonunion because of the richer blood supply, they are more common and are associated with a slightly higher mortality. The fracture line may extend through both trochanters. The amount of displacement is usually small and separation of fragments is not marked. The clinical manifestations are similar to those of fracture of the hip, except that shortening is not as pronounced. Treatment may be effectively carried out by internal fixation (26), traction with the Thomas or Hodgen splint, plaster cast (Fig. 24), or Anderson's "well-leg" traction splint. In some cases, internal fixation with a Neufelt or Jewett nail will be preferable because they enable the patient to be out of bed much earlier. Frequently, however, the outer fragment is too badly cominuted to give good fixation. Weight-bearing is discouraged until union is quite firm. Ordinarily, firm union will take place several weeks earlier than in intracapsular fractures because of the large surface involved and the increased blood supply; both factors will result in the formation of more callus. If shortening occurs, and it often does, the disability may be minimized by using a shoe with a built-up heel on the affected side.



Shaft of the Femur. The type of violence producing a fracture of the shaft of the femur may be either direct or indirect. Shock may be produced by this type of injury and may be as pronounced as in fracture of the neck of the femur. Pain is usually severe and complete disability is present. Because of the depth of the tissue overlying the fracture, tenderness is diffuse; and though considerable swelling is present, ecchymosis is delayed or absent. Measurements between the trochanter and external malleolus reveal a shortening on the injured side unless a fracture exists without displacement. Crepitus will be present, but no attempt should be made to elicit it because of pain and trauma inflicted. Slight and gentle rotary motion of the knee or leg will reveal a failure of the trochanter to move with the shaft. Because of the pain and shock produced by transportation, immobilization should be effected by some type of metal or wood splint *at the scene of the accident* and

Fig. 24. Plaster spica. This cast was applied to a patient with an intratrochanteric fracture but, in general, internal fixation with some type of pin is preferable.

before the patient is transported to the hospital or other suitable place for roentgenograms and treatment. A traction splint, such as the Thomas or Keller, is most effective in preventing and in reducing displacement during transportation. Displacement as well as overriding of fragments is nearly always great, owing to the number and strength of the muscles attached to the femur. The amount and type of displacement depends to a great extent upon the location of the fracture. In fractures of the *upper third* of the shaft, the iliopsoas and glutei muscles tend to abduct and flex the proximal fragment so that it usually lies anterior and lateral to the distal fragment. The deformities of fractures of the *middle third* are apt to be variable, but the proximal fragment usually lies anterior and lateral to the distal fragment as in fractures of the upper third, but with less displacement. The anterior convexity of the thigh is lost. In fractures of the *lower third*, the pull of the gastrocnemius displaces the distal fragment posteriorly. Fractures in this location are occasionally associated with injury to the popliteal artery or nerves; severance of the artery is serious because of the danger of gangrene, but fortunately this is a very rare complication.

Treatment. Simple reduction and immobilization in a plaster cast is not satisfactory, because reduction is difficult to achieve and even more difficult to maintain. Fractures of the shaft are, therefore, usually best treated by suspension and adhesive or skeletal traction. In either case a Thomas splint (Fig. 25) will be found suitable to obtain suspension of the limb. Bending the splint to allow a few degrees flexion at the knee, or the use of the Pierson attachment, will add to the comfort of the patient and to a slight extent encourage the return of motion in the joint. If adhesive traction is used, either a Hodgen or Thomas splint will be found satisfactory. An important feature of the traction lies in the necessity of placing the extremity in a position with sufficient abduction and flexion of the thigh to bring the distal fragment into alignment with the proximal fragment. Moreover, with the thigh flexed, the weight of the body aids in attaining efficient

A B

counter traction. If the fracture is oblique, and there is little overriding, adhesive traction should be adequate to obtain satisfactory results. However, if the fracture is transverse (*usually with pronounced overriding*), *reduction* is much more readily obtained by skeletal traction. Skeletal traction can be carried out by the insertion of a Steinmann pin through the upper third of the tibia, immediately posterior to the anterior tibial spine, or through the os calcis, and application of traction to the stirrup attached to the pin. The application of 30 to 40 pounds of traction usually corrects the overriding in two to three days, at which time spontaneous reduction of fragments frequently occurs, but if not, very little manipulation is necessary to bring the fragments into position. Frequent observations by x-ray may be necessary lest overpull result in separation of the fragments. Attempt need not be made to secure perfect end-to-end approximation; if the two fragments are merely locked at the edge, good results may be expected provided alignment and proper immobilization are maintained. After the fragments are locked end on, the amount of traction should be reduced to 10 to 15 pounds. Regardless of the type of traction used, the splint will have to be suspended in some type of overhead (e.g., Balkan) frame (Fig. 26). In many cases, suspension and traction may be replaced by a plaster cast after three to four weeks; at this time there is no danger of losing the position of the fragments.

In fractures of the middle third of the femur the strong plea made by Sofield (27) to use conservatism in the treatment of fractures is quite applicable, although it is admitted that certain circumstances require *radical treatment.*

If the fracture is located in the *upper third,* traction will have to be maintained in wide abduction with considerable flexion of the thigh so that alignment of fragments may be achieved. Usually, *some type of skeletal traction* as previously mentioned will have to be used. Adhesive traction will not be very useful in fractures in this location but will find its greatest usefulness in the fractures in the *middle third,* care being taken that the posteriorly displaced distal fragment is held forward by the flannel or canvas bands or by a sling attached to the frame in traction. Only slight abduction is indicated in fractures of the middle third.

If the fracture is in the *lower third,* the distal fragment will be so firmly displaced posteriorly by the gastrocnemius muscle that adhesive traction will be inadequate in obtaining proper position of fragments. Skeletal

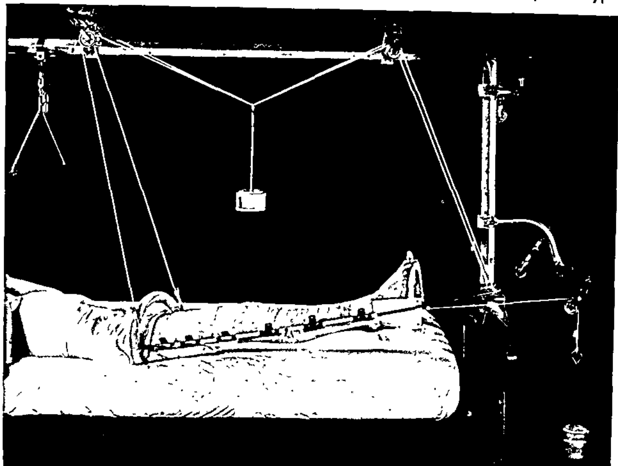

Fig. 26. Buck's extension for traction on the femur. Such traction is useful in fractures of the femur not requiring internal fixation. (After Scuderi, Atlas of Orthopedic Traction Procedures, C. V. Mosby.)

traction is much more efficient, especially because it permits the acute degree of flexion at the knee required to maintain proper position. It may be obtained with a Steinmann pin through the upper end of the tibia. Occasionally it may be wise to reduce the fracture under an anesthetic and apply a plaster spica with the knee flexed. If so, the position of the fragments must be checked frequently by x-ray and the circulation of the leg carefully watched. The pin may be removed in eight weeks and the patient allowed up on crutches with the aid of a walking caliper splint.

The Stader method of fixation of the pins (after placement through the fragments) to a bar external and parallel to the skin is used by some surgeons in order to avoid prolonged hospitalization, but should be used with caution, because such complications as osteomyelitis are relatively common following its careless use in fractures of the femur. Open reduction with internal fixation may be indicated at times, if proper reduction is unobtainable by manipulation alone. In the hands of well-qualified surgeons, open reductions with internal fixation of the fracture should be done early in cases with displacement or soft tissue interposition. Plates and screws are best used in most cases. Transverse or short oblique fractures of the middle third of the femur lend themselves to fixation with a Küntscher rod. This procedure, however, requires a good operative team and adequate equipment.

The *after treatment* of fractures of the shaft of the femur is extremely important. Regardless of the type of traction apparatus used (with the exception, perhaps, of the skeletal fixation method just described), it must be watched daily and adjustments made as indicated. Such precautions include application of pressure over fragments to aid in alignment, watching skin for pressure sores, guarding against knots slipping, use of counter or

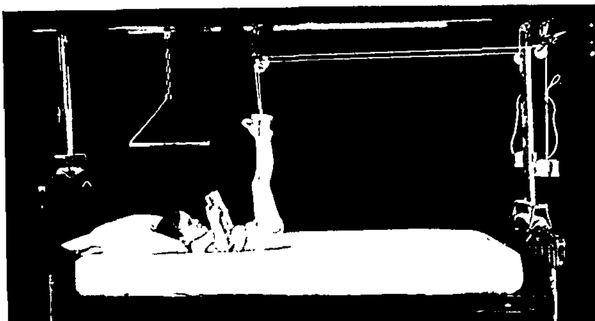

Fig. 27. Bryant's overhead traction for fracture of the femur in children. The injured extremity alone, or both, may be suspended with traction. Sufficient weight is used to barely lift the buttocks off the bed. Suspension and traction of both extremities has the advantage of supplying more stability, although more traction can be obtained if only the injured extremity is suspended. (After Scuderi, Atlas of Orthopedic Traction Procedures, C. V. Mosby.)

secondary traction, and so forth. When traction is chosen as the method of treatment it must be maintained for six to eight weeks, after which time a plaster cast may be applied for an additional six weeks or more depending upon the type of fracture and rate of healing. However, it is usually desirable, eight to twelve weeks after the fracture, when union is fairly solid, to allow the patient up in a convalescent caliper splint which takes the weight off the foot. Actual weight-bearing should not be allowed to any significant degree up to six months following fracture. Active and passive motion as well as massage should be instituted as soon as possible without disturbing the traction and position of fragments.

Compound fractures of the femur are uncommon except in penetrating bullet or shrapnel wounds because of the large amount of muscle surrounding the bone. Usually, the amount of bone projecting beyond the skin is so small that extensive débridement may not be necessary. Traction and immobilization may be carried out as outlined above. If skeletal traction is used, the wire or pin must not be inserted through the bone near the fracture line because of the danger of osteomyelitis.

Fractures of the Shaft of the Femur in Children. Most fractures of the femur sustained by children are located in the shaft. Up to the age of five or six years they are best treated by Bryant's overhead suspension and traction (Fig. 27). Adhesive is applied up to the level of the fracture, the extremity is then suspended upward at right angle to the bed, and sufficient traction applied to just raise the buttocks from the bed. Immobilization in traction for four weeks followed by fixation in a plaster spica for four or five more weeks usually is sufficient immobilization to begin weight-bearing.

For children over six years of age the Russell traction, consisting of adhesive traction from the knee down with flexion of the knee created by a sling, will be found very useful. This mechanism can often be used advantageously in adults, particularly when a maximum amount of traction is not needed. Its great advantages are simplicity and freedom of movement by the patient. One disadvantage is that it requires constant care and adjustment.

The Knee. FRACTURE THROUGH THE FEMORAL CONDYLES. This fracture may be inflicted when violence of unusual degree is sustained by a fall upon the feet or knees. The condyles are usually split in a T fashion so that the fracture extends into the joint; commonly the fragments are displaced posteriorly and spread apart. Such a fracture is serious because of the difficulty in obtaining adequate reduction and in preventing stiffness or ankylosis of the knee. Skeletal traction, obtained by a Kirschner wire inserted through the tubercle of the tibia, is usually the treatment of choice because in this way sufficient flexion of the knee may be secured to relax the pull of the gastrocnemius. Frequently, operative reduction with some type of fixation of fragments will be indicated or necessary. Closed reduction by instrumental manipulation will often be indicated and successful, although difficulty will usually be experienced in maintaining reduction.

Unless the articulation of the joint is restored to normal, a severe arthritis will rapidly result. For this reason, accuracy of reduction is imperative. If this is not obtained by closed reduction, open reduction with internal rotation should be resorted to. Long screws or a right-angle blade plate can be used advantageously in many of these cases.

SEPARATION OF THE LOWER EPIPHYSIS OF THE FEMUR IN CHILDREN. This injury is encountered as a result of violent trauma, such as a bad automobile accident. The distal fragment is displaced anteriorly. Reduction should be carried out under anesthesia and is usually accomplished with ease. The extremity is immobilized in a plaster cast with the knee flexed. An open reduction should not be done because of the danger of nongrowth unless adequate reduction is not obtained by the closed method.

FRACTURE OF THE PATELLA. This is a common injury and is usually sustained by a direct blow over the knee. Effusion into the joint is usually profuse and contains a large amount of blood. The patella may be comminuted with or without displacement, but the fracture is usually transverse. When complete, the lateral tendinous attachments of the joint ligaments are usually torn and wide separation of the fragments is produced. In such cases, operative reduction is adopted (Fig. 28) unless sufficient injury has been in-

Fig. 28. Fracture of the patella. Left, wide separation and pronounced hemarthrosis due to intra-articular bleeding is noted. Operative reduction is necessary. At this time the soft tissue tear in the retinaculum must likewise be carefully reapposed and sutured. Right, postoperative films show anatomic reapposition of the patellar fragments, held in place by a loop of wire.

flicted to the skin about the patella to jeopardize asepsis, a complication which commonly occurs. The danger of infection in such a situation may be so great that it will be necessary to delay operation for many days until the skin has healed. Adequate fixation of the fragments by open operation allows early motion, thereby tending to prevent stiffness of the knee, which is a frequent complication of fractures of the patella. Fixation of bone is usually accomplished by wire sutures. Occasionally, the patella will have to be removed if the comminution is severe. Wire sutures through small drill holes in the anterior surface of the patella are very effective; the solidity of the repair obtained by metal sutures allows early motion and is, therefore, very advantageous in fractures about the knee. The tear in the capsule and quadriceps aponeurosis *must* be repaired. Fixation of fragments must be so secure as to allow active motion in a few days and weight-bearing in two or three weeks. If no separation of fragments exists, simple fixation of the knee by a thin plaster cast will be the method of choice. Excision of small distal fragments and suture of the patellar tendon to the proximal fragment is sometimes used.

Dislocation of the Patella. This is uncommon and usually occurs in childhood, but tends to recur with only slight violence. The patella is dislocated outward. It may occur in adults, particularly women, when falling upon the knee with force exerted outward on the patella. Reduction is easily effected and usually without an anesthetic. In recurrent dislocation, operative repair may be indicated.

Dislocation of the Knee. This is a rare injury and is sustained only by severe violence. Injury to the peroneal nerve or popliteal vessels is frequently sustained simultaneously. The dislocation may be one of three types, i.e., with the head of the tibia displaced anterior, posterior, or lateral to the femur. The collateral and cruciate ligaments are usually torn, thus allowing remarkable mobility. The anterior type of dislocation is the most common and is usually produced by hyperextension. Reduction is easy, but fixation must be maintained in a plaster cast for five or six weeks to prevent a relaxed joint which is so apt to follow such injuries: therefore, open operation with repair of the ligaments at time of injury is frequently advisable.

Rupture of Cruciate Ligaments. Rupture of the cruciate ligaments is fortunately not common but such minor injuries as stretching and tearing are no doubt sustained in many sprains and fractures about the knee, particularly when the knee is overextended and rotated. Unusual mobility of the knee, particularly in the anteroposterior direction, is the most diagnostic sign. If the anterior cruciate ligament is torn, the mobility is apt to be most prominent when the knee is extended. When the posterior cruciate is torn the mobility will be most marked when the knee is flexed. For treatment of torn cruciate ligaments, immobilization of the knee in a plaster cast for about six weeks is probably the method of choice. Operative repair of neglected cases is recommended by some surgeons and may be facilitated by the use of fascial strips.

Injury to the Semilunar Cartilages of the Knee. The semilunar cartilages are flat, circular structures which are attached by their ends near the center of the joint and furnish a concavity for articulation of the condyles of the femur. Their lateral attachments to the capsule and lateral ligaments are so insecure that detachment or injury at this point is frequent. The medial cartilage is injured much more frequently than the lateral. The injury may consist of a detachment, tear, or a crush and is usually sustained by sudden extension of the joint with twisting. Considerable pain is usually experienced at the time of the initial injury. If a piece of cartilage is torn off or displaced there may be "locking" of the joint with inability to completely extend it. Tenderness is usually present along the articular surface of the tibia on the medial side. Commonly, reduction occurs spontaneously, in which case the characteristic "locking" will be absent. Diagnosis may then be difficult and can be made on the basis of recurrent attacks of pain in the knee without x-ray changes. Acute injury of the cartilage is usually associated with an accumulation of fluid which may be bloody or serous in type. Many surgeons strongly recommend aspiration for practically all types of effusion following trauma (Shands) on the basis that

bloody fluid, if not removed, encourages the development of adhesions.

Once a semilunar cartilage has been torn and has produced locking, surgical removal is indicated, as the cartilage will not heal because of absent blood supply; moreover, recurrences are inevitable. Surgery can be performed at the convenience of the patient unless the locked knee cannot be unlocked by manipulation, in which case there should not be too much delay (several days).

SPRAIN OF THE KNEE. Injuries of this type are common and consist primarily of a stretching or tearing of the lateral ligaments which are, in reality, thickened portions of the capsule of the joint. Fluid commonly accumulates within the joint so that the patella is floating and the normal joint landmarks are obliterated (acute traumatic synovitis). Ecchymosis may be present. Flexion of the joint is painful, but unless the semilunars are likewise injured, extension is free and painless. Lateral mobility of the knee may be increased because of the tearing or stretching of the ligaments. The internal lateral ligament is most often affected. It is particularly important to get an x-ray of the joint if disability is very pronounced because a sprain fracture (i.e., avulsion of a small fragment of bone at the attachment of the ligament) is so often present.

Treatment consists of rest of the affected part for two or three weeks, depending upon the severity of the sprain. In severe cases it may be necessary to resort to immobilization with a plaster cast or similar type of fixation. The joint should be aspirated if fluid is present.

The Tibia. Under this heading will be included fracture of the upper end of the tibia and fracture of the shafts of the tibia and fibula.

UPPER END OF THE TIBIA. Fractures may be sustained through either or both condyles of the tibia. They are commonly due to direct violence when the patient is struck by the front bumpers of an automobile; on such occasions they are called "bumper fractures." The fracture line in the "high bumper fractures" almost invariably extends into the joint. If the fragment includes the condyle or a small portion thereof, it is usually displaced downward. There is nearly always a concomitant injury to the cartilage and occasionally of the peroneal nerve with foot drop. Pain is unusually severe. The joint is filled with fluid, the greater part of which is blood. It is particularly important to obtain as complete reduction as possible, because of the danger of development of a permanently painful joint. Furthermore, if the condyle is not replaced upward into its normal position, genu valgum or genu varum is apt to develop, depending upon which condyle is displaced. Traction will usually be the most adaptable method of treatment. Reduction of fragments by direct manipulation is difficult, but may be facilitated by the application of a clamp over the fracture site to compress the fragments into position. Frequently reduction will not be possible by traction and manipulation, making it necessary to resort to operative reduction. On account of the active blood supply in this region, union takes place rapidly, but weight-bearing should not be allowed for 12 to 18 weeks because of the tendency for the soft callus to give way, with a resultant knock knee or bowleg deformity. "Bumper fractures" now occur lower down on the leg because cars are made with lower bumpers. Frequently, therefore, they do not involve the joint.

SHAFTS OF THE TIBIA AND FIBULA. Fractures of the shafts of the tibia and fibula may occur at any level, but are most frequent at the junction of the lower and middle thirds where nonunion is also most common. The fractures may be transverse, oblique, or spiral, with or without comminution. The lower fragment of the tibia is usually displaced posteriorly. The fractures may be caused either by direct or indirect violence. In the former case, as when the direct blow is sustained, the fracture in the two bones is apt to be at the same level. In indirect violence, the tibia usually breaks near the junction of the middle and lower thirds, and the fibula at a higher level. For that reason it is particularly important that the x-ray include the entire leg from the ankle to the knee. Diagnosis of a fracture of the tibia is usually made without difficulty because the bone is subcutaneous over its entire anterior surface. The patient is unable to walk unless the fracture is impacted or incomplete. Pain and local tenderness point to the location of the frac-

ture. Swelling and ecchymosis develop after a few hours. When the fracture affects only the upper two thirds of the fibula, the manifestations will be less severe; the patient may be able to walk with only a moderate amount of difficulty, since the fibula has little to do with weight-bearing of the body.

TREATMENT. There are several anatomic features which must be borne in mind during the treatment of a fracture of the tibia. For example, the articulation at the ankle and knee must be restored to the normal position; otherwise a painful joint with disability may result. It is essential then that proper alignment be obtained in the anteroposterior, as well as the lateral, plane (28). A mild degree of shortening is tolerated without detriment to the patient as far as function is concerned. However, a posterior bowing (i.e., convexity posteriorly) is particularly disabling and for that reason it may be wise to overcorrect this deformity at the time of reduction by producing a mild anterior angulation. Usually the fragments can be reduced manually without difficulty and molded into position with the patient under proper anesthesia. Flexion of the knee frequently facilitates reduction. If reduction is obtained, it is obviously important to maintain position of the fragments while the cast is being applied. Care must likewise be taken to avoid medial and posterior bowing. The foot is placed at right angles to the leg and in mild inversion. If the fibula alone is fractured, immobilization in a cast for six weeks should be sufficient to permit painless weight-bearing. However, if the tibia is fractured, immobilization in a cast must be maintained for at least 10 to 12 weeks. Following this, the patient is allowed to walk with crutches, weight-bearing being permissible and encouraged, particularly if a walking iron has been incorporated into the cast (Fig. 29).

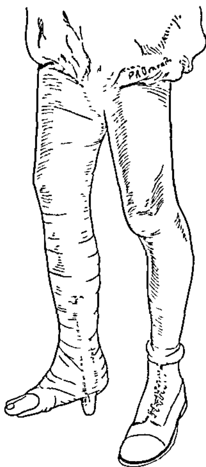

Fig. 29. Skin (unpadded) cast with metal foot piece incorporated in the cast. This is particularly useful in patients with delayed union of the tibia and fibula. The skin cast is often used as a primary form of treatment; its fixation is more secure and it permits ambulatory care.

Occasionally, and particularly when both bones are fractured or the tibial fracture is an oblique one, correct apposition of fragments cannot be maintained adequately by simple reduction and the application of a plaster cast. In such instances, it may be advisable to insert a Kirschner wire through or above the os calcis and secure constant traction to the stirrup connected with the wire (Fig. 30). Traction by this means encourages correct alignment and maintains a correct position for the foot and ankle. The alternative method is to insert a Kirschner wire through the lower fragment as well as the upper fragment, to reduce the fracture by manipulation under anesthesia, and then to incorporate the pins into the cast applied from the toes to mid-thigh while traction and reduction are being maintained (Fig. 31). Primary open reduction with internal fixation is recommended by some surgeons, especially when the tibial fracture is oblique in type.

Delayed union or nonunion is fairly common in fractures at the junction of the middle and lower thirds, partly because of deficient blood supply, but particularly because the lack of muscular attachment allows dissipation of the clot. Accurate reduction lessens

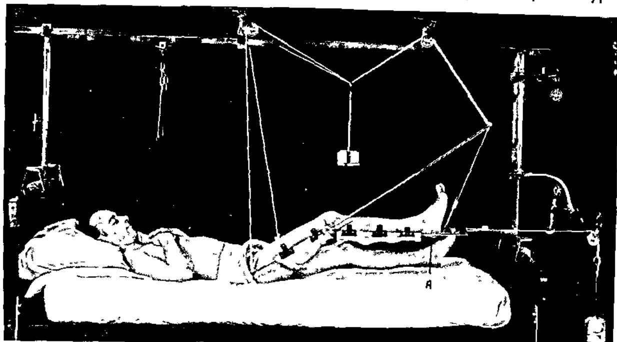

Fig 30. Thomas splint and Pearson attachment. This apparatus with a Steinmann pin through the os calcis at point A is commonly used for "both bone" fractures of the tibia and fibula with severe overriding and comminution. (After Scuderi, Atlas of Orthopedic Traction Procedures, C. V. Mosby.)

A B C D

Fig. 31. *Fracture at the distal third of the tibia and fibula. A and B reveal marked* communication as well as moderate angulation and overriding. To obtain good reduction and proper immobilization, double pin fixation was indicated. *C and D, one pin was placed through the os calcis and the other* through the upper third of the tibia. A boot cast was then applied from the base of the toes to the knee, with the foot at right angle to the tibia.

the possibility of nonunion. If, after six to eight weeks of immobilization, there is no evidence of union, the deposition of callus may frequently be encouraged or hastened by allowing the patient to bear weight on the foot, providing, of course, a close-fitting plaster cast (skin cast) from the toes to the midthigh maintains position and alignment (see Fig. 29). This method may also be used as the primary procedure when displacement is not marked. Griswold (29) has emphasized the value of the ambulatory treatment with a nonpadded cast and walking iron, in fractures of the tibia and fibula, in the prevention of bone atrophy and nonunion. Although weight-bearing in a walking cast is permissible in six weeks, weight-bearing without support should not be allowed for four months. Bone grafts are often effective in nonunion (30), and at times are advisable.

Open (compound) fractures occur more often in the tibia than in any other bone, chiefly because the tibia is subcutaneous over such an extensive area. If the break in the skin is small and there is reason to suspect that very little and unimportant contamination has taken place, the fracture may be treated as a simple fracture with reduction and application of a plaster cast or splint as indicated after the area has been mechanically cleansed and closed. However, if much bone has protruded, or if the wound is large and obviously seriously contaminated, thorough débridement must be done immediately unless contraindicated by serious injury elsewhere. Extreme care must be taken in the removal of foreign bodies, dead tissue, blood clots, and small fragments of bone. After the fragments are reduced, the wound including the skin is closed. Rarely is a drain justified. Immobilization is then obtained by a plaster cast, skeletal traction, or double pin fixation, as indicated. If a cast is used, a window may be cut in it at the site of the fracture so that the wound may be inspected, but only if fever or undue pain develops. If the injury is more than seven or eight hours old, but with no evidence of infection, débridement should still be carried out. In serious cases, continuous traction with metal pins and some type of frame may be indicated (see also p. 463). Most surgeons do not recommend prophylactic use of antibiotics, but if infection develops, antibiotics are indicated; a culture should be obtained and sensitization tests carried out so that the most effective antibiotic can be utilized. If infection is significant, the wound should be opened for drainage.

The Ankle. Because of the relatively small size of the structures existing in articulations at the ankle and the great weight of the body, injuries in this region are common and usually produced by indirect violence. As will be discussed later in the text, injuries involving the joints (particularly of the tarsal bones) are most serious, since permanent dysfunction due to pain is apt to develop; position of fragments becomes very important in such injuries.

POTT'S FRACTURE. Percivall Pott, in 1768, in his "Remarks upon Fractures and Dislocations" described an uncommon fracture which originally bore his name. It is a fracture of the fibula, two to three inches above the external malleolus, produced by eversion and associated with the tearing of the internal, external, or deltoid ligament extending from the astragalus and os calcis to the internal malleolus. Occasionally, only a small flake of bone is avulsed from the internal malleolus while the deltoid ligament remains intact. There is an associated lateral subluxation of the astragalus. However, over the years the term "Pott's fracture" has been loosely used to describe any fracture of the ankle involving any or all malleoli. This common usage has completely supplanted Pott's original description of the fracture which almost 200 years ago first bore his name.

The most common type of Pott's fracture consists of a fracture of the fibula one or two inches above the ankle and an avulsion of the tip of the internal malleolus. Such fractures are produced by a variety of forces including inversion, eversion, hyperflexion, hyperextension, rotation, and perhaps an additional factor of compression of the foot against the leg. Often several of these factors act together. The primary lesion resulting from such injury is a displacement of the astragalus on the tibia. Since the two malleoli are firmly attached to the astragalus by strong ligaments, displacement of the astragalus may carry adjacent fragments with it. Occasionally, the fracture extends through the entire shaft of the tibia as well as fibula a few centi-

meters above the joint. This usually occurs, however, only when the trauma is severe. If the foot is also forcibly extended (i.e., in plantar flexion) during the injury, a posterior fragment of the tibia may break off, including a considerable portion of that bone, giving rise to what is now called a trimalleolar fracture, which years ago also bore the name "Cotton fracture," after Frederick Cotton of Boston who contributed much to the description and treatment of this fracture. Although the ligamentous attachment between the lower portions of the tibia and fibula is strong, there is a tendency toward tearing or stretching of this ligament with separation of the two bones and a mild lateral displacement of the astragalus. One type of deformity of extreme importance in Pott's fracture is a posterior dislocation of the astragalus, at the tibial articulation. This is particularly apt to occur if the injury is produced by forcible extension of the foot. Less commonly, a Pott's fracture is sustained by forcible adduction or inversion of the foot. In this case, the external malleolus is pulled away and the internal malleolus is broken by infringement of the astragalus. Occasionally, the entire shaft of the tibia is broken.

The clinical manifestations of Pott's fracture are extremely variable. The cardinal signs of fracture (as described on p. 457) may be present, but if the fracture is limited to the fibula and not complete or displaced, the patient may be able to walk with only moderate difficulty (Fig. 32). Local tenderness will, of course, be present over the external malleolus and perhaps over the lower border of the internal malleolus. However, there may be no way of differentiating this type of a fracture from a sprain without the aid of an x-ray, which should always be taken in such instances. There may be an obvious eversion or inversion deformity, depending upon the mechanism of fracture. If the fracture includes the shaft of the tibia, the patient will, of course, be unable to bear any weight whatever upon his foot, unless impaction exists. The backward dislocation of the astragalus may not be demonstrable, although the foot is almost always held in a position of extension (i.e., plantar flexion). Part of the swelling about the ankle is accounted for by the bloody effusion into the joint which is somewhat greater than expected. The swelling tends to mask deformity and obliterate the bony landmarks.

Fig. 32. Fracture of lower end of the fibula. The external malleolus is fractured but very little displacement is present. There is no visible fracture of the tip of the internal malleolus, but the ligament may be torn. The leg should be put in a cast for four or five weeks with the foot in inversion.

The *treatment* of most patients with Pott's fracture is simple, chiefly because reduction is rarely difficult. If the fragments of the fibula buckle inward toward the tibia, or if a chip of the internal malleolus is displaced downward, or if fracture of the tibia with displacement exists, reduction under anesthesia will be necessary. Much better results are obtained if reduction is performed as soon as possible after the accident and not delayed until after the swelling becomes minimal, as was practiced by many surgeons years ago. Proper reduction consists primarily of *inversion of the foot, traction, and flexion of* the foot to a right angle with the shaft of the tibia, and the application of a cast as mentioned above. It is important that an x-ray be taken after reduction to be sure that no deformity remains. Attention is directed particularly to posterior displacement of the astragalus because this type of deformity is frequently overlooked. The simple procedure of placing the foot in a right-angled position tends to correct most of this deformity. Application of a plaster cast from the toes to the knee is the most desirable type of fixation; in fractures with marked displacement, the knee, too, must be immobilized. Fracture of the posterior lip of the tibial articular surface is not uncommon and requires special precautions for an anatomic reapposition of the fragment. Any displacement produces an irregularity of the joint surface with a resulting swollen, painful joint and probable ultimate surgical ankylosis. For this reason, if more than 25 per cent of the joint surface is broken off, careful surgical reapposition is essential, with screw fixation (Fig. 33). The surgical anatomy and technic has been described by *Scuderi and Schrey in 1948. Immobilization* of the fracture is necessary for eight to ten weeks followed by physical therapy, but no weight-bearing under four months.

The toes must be watched carefully for numbness, tingling, coldness, paralysis, and so forth, because any great increase in swelling could easily interfere with the blood supply to such an extent as to jeopardize the structures distal to the obstruction. Since immobilization and proper reduction will practically always relieve the pain of a fracture within a few hours, subsequent development

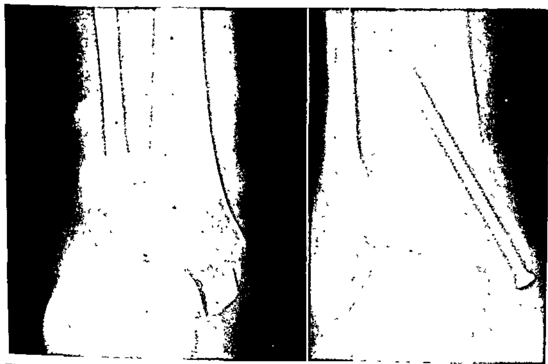

Fig. 33. Bimalleolar fracture of the ankle. Left, the astragalus is subluxated laterally and the medial malleolus has completely lost its buttress function. Unless the ankle mortice is anatomically replaced, a painful ankle will result from a traumatic arthritis. Right, fixation with a screw was chosen here as the method of treatment, but is not necessary in the majority of bimalleolar fractures.

Fig. 34. Compound (open) dislocation of the ankle before and after reduction. Healing occurred without infection and the functional result was good. (St. Louis City Hospital.)

of pain of more than a slight degree may warrant splitting or bivalving of the cast, thereby allowing room for excessive swelling.

If the fracture involves only the external malleolus (i.e., the fibula), the cast may be removed in five to six weeks, the ankle strapped and bandaged, and weight-bearing allowed with crutches. If the shaft of the tibia is fractured, the immobilization should be maintained for eight to ten weeks. Weight-bearing with the aid of crutches should be started cautiously. The application of heat by baking, and the like, will frequently be efficacious in relieving the stiffness and chronic pain so frequently complained of in fractures about the ankle. Such measures will also tend to shorten the period of disability.

DISLOCATION OF THE ANKLE. Posterior dislocation and a mild lateral dislocation may occur in Pott's fracture, as already described. On rare occasions complete dislocation, usually posterior or lateral, may occur without fracture (Fig. 34). Complete dislocation is usually accompanied by fracture of the external malleolus or tip of the tibia, perhaps by both. Reduction of the dislocation is not difficult, but if there is much comminution of the tibia and fibula, considerable difficulty may be experienced in replacing these fragments. Immobilization must be maintained for four weeks, at least. If there has been an accompanying fracture of the entire shaft of the tibia, immobilization for a longer time will be required.

On rare occasions a dislocation of the ankle is *compound*. Treatment is not different from that of a compound fracture. As soon as possible, the wound is subjected to thorough débridement and irrigation, followed by reduction of the dislocation and closure of the wound. Immobilization is best obtained by a plaster cast, but the wound must be observed closely for the possible development of an infection, which, if serious, may lead to gangrene and amputation.

SPRAIN OF THE ANKLE. This injury is almost invariably sustained by forceful plantar flexion and inversion of the foot beyond normal range of motion and is commonly inflicted by throwing the weight of the body on the "turned" ankle, usually after catching the heel on a stair or stepping in a hole while running. The injury consists primarily of a tearing of the external lateral ligaments and is thus produced by a force opposite to that producing a typical Pott's fracture. If the external lateral ligament resists tearing, the tip of the external malleolus may be torn off, constituting what is called a sprain fracture.

The pain inflicted by a severe sprain may be as severe as that produced by a fracture and may be so disabling as to entirely prevent walking. Usually, however, the pain produced by a sprain decreases within a day or two to the extent that at least a slight amount of weight-bearing is possible. Forcible pressure against the heel does not produce appreciable pain when a sprain is present but is quite painful when there is an associated fracture of consequence. Swelling of soft parts about

: injured ligaments occurs within a few ours and a variable amount of ecchymosis ll develop. This ecchymosis is usually less tensive than that associated with a fracture. ne joint not infrequently fills with fluid or ood, but this is usually indicative of injury the joint structures. The *tenderness asso- ated with a sprain is apt to be diffuse* over e injured external lateral ligaments, in con- ast to the local tenderness associated with fracture. Such signs of fracture as crepitus, normal mobility, and deformity obviously ill be absent. The disability sustained by a rain is usually not as severe as that asso- ated with a fracture, particularly in regard weight-bearing. On a few occasions, how- 'er, a badly sprained ankle will produce a ainful joint for many weeks or months in ontrast to the relatively short duration of ain after a fracture confined to a minor bone. he reasons for this difference are not always ear.

The type of *treatment* is variable, depend- ig upon the severity of the injury. If the pa- ent is seen immediately after injury, the ap- lication of cold packs for an hour or two ombined with complete rest of the part may ssen the amount of hemorrhage and exuda- on of serum. The most important feature, owever, is immobilization of the joint. Strap- ing with adhesive in an overlapped fashion ntil the entire joint and lower third of the g are encased in an adhesive splint is usu- lly quite efficient. A nonadhesive elastic ace) bandage or elastic adhesive (elasto- last) is comfortable and effective. This im- nobilization should be carried out with the oot in the position of right-angled flexion and version so as to afford rest for the external ateral ligament which is usually the ligament orn in a sprained ankle. If the internal liga- nents are torn, as happens only occasionally, he foot should be immobilized in inversion. After two or three days' rest, the patient may begin to walk about, using a cane or a crutch as indicated. The application of heat for 30 to 45 minutes, two or three times a day, en- courages hyperemia and is efficient in reliev- ing the pain and promoting healing. The pa- tient should not be encouraged to increase the activity of the joint beyond the production of pain, especially during the first 10 days when healing is taking place. The adhesive splint usually becomes loose after four or five days and must be reapplied. It should be worn as long as pain is experienced during walking and as long as it affords appreciable relief. When the sprain is severe, immobilization with an adhesive splint will not relieve the pain and it will be obvious within 24 hours that more secure fixation is necessary. In this case, the application of a light plaster boot for a week or even more will not only de- crease the pain but will promote healing and allow the patient to walk comfortably with the aid of crutches. After the plaster cast is removed (seven to ten days) the ankle is strapped and the patient allowed to walk more and more each day, depending upon the amount of disability. Obviously the treatment of a sprain should not be undertaken without thoroughly excluding fractures, particularly by x-ray.

One must never lose sight of the fact that a true sprain results in tearing or disruption of the continuity of an important ligament. Healing of ligaments is slow compared to other tissues because of their meager blood supply, and unless healing is complete, a permanently insufficient stability results which leads to recurrence of the original symptomatology.

The injection of novacaine (recommended by some surgeons) abolishes pain and leads to a false sense of security. As it exerts no beneficial effect on the healing of the torn ligaments (and may actually lead to added trauma) it should be used in only the most minor cases.

The Foot. FRACTURES OF TARSAL BONES. These injuries may be very disabling, and consequently require utmost care in treat- ment. Fractures of the tarsal bones include chiefly the astragalus, os calcis, and scaphoid; they are usually sustained by a fall in which the foot receives the impact. The type of frac- ture varies from a single line to a comminu- tion or crushing. The manifestations are so atypical that an accurate diagnosis can rarely be made without an x-ray. Tenderness may be diffuse, as is also ecchymosis and swelling. Walking is very painful, if possible at all. Treatment consists of molding of the frag- ments into position, if possible, and immobi- lization in a plaster cast for four weeks or more. All fractures of the tarsal bones are

serious because of the frequency of permanent disability, due to pain. This is particularly true of fractures of the *astragalus* (*talus*), which are so often followed by persistent pain that many surgeons advise arthrodesis (to produce ankylosis) as the primary treatment immediately after the injury. Occasionally fusion of the ankle and subastragaloid joint is necessary in cases where inadequate reduction or a nonunion has resulted. This permits the patient to have a painless and stable joint. Astragalectomy has fallen into disrepute as fusion is an infinitely better solution to the problem. Fractures of tarsal bones are common in the naval personnel during wartime, being sustained when a torpedo explodes below decks (see Ch. 42).

Fracture of the *os calcis* is apt to be sustained in such a way that flattening of the arch results. It is a frequent injury most common in roofers and painters who fall from a height, striking on their heels. This is an extremely disabling fracture and should be corrected as completely as possible. The flattening of the foot is due to force transmitted to the calcaneus by the wedge-shaped portion of the talus. The calcaneus is crushed and spread laterally, the lateral fragment or fragments coming to rest beneath the lateral malleolus and compressing the structures which pass behind and beneath the malleolus. Marked comminution is a rule, with fracture lines running into and distorting the astragulocalcaneal joint. The posterior portion of the os calcis is forced upward and held by the Achilles tendon. Böhler has laid great stress upon the tuberosity-joint angle, otherwise known as the salient angle. This is the angle between a line drawn from the upper part of the tuberosity of the calcaneus to the highest point of the bone and another from the anterior angle to the highest point. These two lines normally make an angle open posteriorly of 20 to 40 degrees. Following flattening of the bone in fractures, this angle becomes zero or even negative. Böhler regards restoration of this angle as of primary importance in treatment. Reduction of the fracture requires strong traction by a pin or wire through the upper portion of the os calcis, combined with pressure on both sides to reduce the spreading of the impingement of fragments upon the structures below and behind the lateral malleolus. Traction or skeletal fixation in plaster should be maintained for at least 8 to 10 weeks in minor cases, and 14 to 16 weeks in the more severe cases, after which weight-bearing in a skintight cast is permissible. Neglected or unsuccessfully treated fractures may require operative removal of bone from beneath the lateral malleolus and fusion of the astragulocalcaneal joint to reduce the disability from traumatic arthritis.

In general, results are poor, particularly when comminution and displacement of fragments exist; in such cases, healing without at least a certain degree of disability (especially pain) is rarely achieved (Dickson and Diveley, 31). There is much disagreement (32, 33) as to whether conservatism or operative procedures are advisable in fractures of the os calcis but, in general, the former is distinctly preferable.

Dislocation of the Tarsal Bones. A dislocation of the tarsal bones may occur, but is uncommon. The astragalus is the bone most often affected. If a severe blow is sustained on the ball of the heel while the foot is plantar flexed, the astragalus may be thrust completely out of position. So much difficulty may be experienced in exerting enough traction on the foot to allow for replacement of the bone that section of the Achilles tendon may be necessary.

Fractures of the Metatarsal Bones. Fractures of these bones are not infrequent, but dislocation is extremely uncommon because the metatarsals articulate with the tarsals at different levels (Fig. 35). Any one of the metatarsals (perhaps most commonly the first and fifth) may be fractured at any point in its shaft. The distal end of the bone is apt to be displaced anteriorly. Walking is rarely possible on account of pain. Swelling and ecchymosis may be mild. Displacement of fragments can and should be corrected by manipulation under anesthesia. Immobilization by a plaster cast extending to the upper third of the leg is usually the most logical treatment, although occasionally adhesive strapping will offer sufficient immobilization. Weight-bearing without the cast should not be allowed for six weeks. Nonunion and persistent pain are uncommon. "March" fracture, which involves the metatarsal bones and is

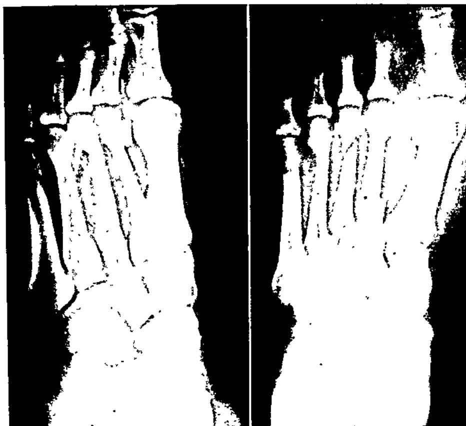

Fig. 35. Fracture of the metatarsal bones. Four bones are fractured, two in two places. Two views reveal very little displacement. Immobilization in a plaster boot is the preferred method of treatment, but in this patient weight-bearing should not be permitted for 8 to 10 weeks.

sustained so commonly during military training, is discussed in Chapter 42.

FRACTURES AND DISLOCATIONS OF THE PHALANGES. Fractures of the phalanges of the toes are common. The distal phalanges of the first and fifth toes are the ones most commonly affected. The injury may be of a crushing type, but more often the patient gives a history of having stubbed his toe in the dark. The pain experienced at the time of injury is usually severe. Local tenderness is pronounced; pressure against the end of the toe is invariably extremely painful. Ecchymosis almost always develops after a few hours. The treatment is unsatisfactory, considering the fact that the injury is so trivial. For fractures other than those in the great toe, an attempt may be made to immobilize the fracture against the uninjured toe. However, if this fixation is inadequate to relieve pain, as it commonly is, it may be preferable to apply a plaster cast with the tip of the cast extending past the end of the toes. For fractures in the great toe, a plaster cast is almost always indicated. The cast may be removed in two or three weeks.

Fractures of the phalanges of the second, third, fourth, and fifth toes are of little clinical significance in walking since displacements and nonunions do not lead to any noticeable disability. However, fractures of the phalanges of the large toe are of considerable clinical importance because of the important role it plays in walking. It is the propulsion power of the large toe that gives human beings the spring in their walking, and it is the flexion power of the large toe that permits walking up inclines without difficulty. For this reason, anatomic reduction and fixation is most essential, and open reduction with pin fixation is indicated in some cases. Irregularity of the metatarsal phalangeal joint must be overcome, otherwise a disabling traumatic arthritis may result.

Dislocations of the phalanges are usually confined to the great toe and consist of dorsal

dislocation at the metatarsophalangeal joint. They are readily reduced by sharp flexion and simultaneous pressure downward at the base of the first phalanx until it slips over the head of the metatarsal. If the flexor tendon has slipped in between the metatarsal head and the phalanx, reduction may be impossible and open reduction required.

THE SPINE AND RIBS

Fractures of the vertebral column may be divided into those of the dorsolumbar region and those of the cervical region. The sacrum and coccyx are discussed under the pelvis.

Dorsolumbar Spine. Of the twelve dorsal and five lumbar vertebrae, the most important ones are those of the lower dorsal and lumbar region, since these are the most movable. The upper dorsal vertebrae are held rigidly by the ribs and are less subject to injury.

COMPRESSION FRACTURE. The most common site of fracture is the body of the vertebra, which is crushed or compressed, hence the frequent use of the term compression fracture. The injury is caused by forced flexion or force applied to the spine while flexed and is often due to a fall with the weight of the body striking the buttocks or feet or a heavy weight falling on the stooped shoulders. In many cases, however, the degree of force is apparently slight. Dislocation of dorsolumbar vertebrae is rare except in severe injuries. Injury to the spinal cord is also encountered only in the more serious fractures and is discussed in Chapter 27. Occasionally associated with spine injuries are abdominal symptoms, which simulate general peritonitis (e.g., distention, vomiting, and abdominal rigidity). If intraabdominal injury is excluded, these manifestations are due to reflex ileus or to retroperitoneal hemorrhage.

The *clinical manifestations* of a compression fracture may be so slight that the lesion is overlooked. Spine injury should be suspected whenever the patient has fallen so that the body weight has been transmitted to the spine, or when force has been applied which might have flexed the spine acutely, such as overturning in an automobile. Deformity may be absent. Local tenderness at the level of the injury and pain on movement may be the only signs. If unrecognized, these fractures may heal spontaneously and result in persistent back pain. An x-ray should be obtained, particularly in the lateral view, in order to demonstrate a compression fracture (Fig. 36). It should be emphasized that the designation of back sprain, which is often applied to many of these injuries, should not be made unless adequate x-ray study has failed to reveal an injury to bone.

The important feature of *treatment* consists of prolonged immobilization in a hyperextended position so that solid bone will be deposited without altering the alignment of the vertebrae. This will prevent further injury to the cord and will even relieve such pressure as may already be present, by restoring the fracture to more nearly normal position. In general, transporting a patient with a spinal injury in the position in which he is found will be a safe policy to adopt. However, hyperextension is easily achieved face down with the vertebral column bowed into extreme lordosis or, if he is being carried supine, a large blanket roll must be placed under the small of the back to achieve the same effect. If a flexion deformity (kyphosis or dorsal angulation) is already present, reduction by forceful or gradual hyperextension of the spine is first carried out. In the former case an anesthetic will be necessary; in the latter method an adjustable type of angulated Bradford frame will be required. If no deformity is present, the patient is placed prone (face down) over a canvas strip and a plaster body cast applied in the hyperextended position. In such a cast the patient may be allowed up within a few days, provided he is comfortable and in no pain. If gradual hyperextension is instituted or if other injuries make bed rest necessary, the cast may be omitted by placing the patient in the supine position over a Bradford frame bent at the site of fracture. Detailed studies by Baab and Howorth (34) reveal that, with average immobilization, 94 per cent of spine fractures gradually recompress to their original deformity, three to six months later. To prevent this, a special hyperextension jacket has been devised by Fisher and Maxwell (35).

Fractures of other parts of the vertebrae—such as the spinous or transverse processes,

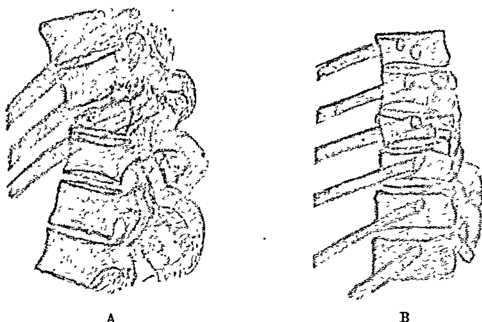

Fig. 36. Compression fracture of the body of the ninth dorsal vertebra in a 53-year-old woman who fell out of a second story window. The illustrations are drawings made from the lateral x-ray films, A, before and B, after reduction. The patient was hyperextended over a bent Bradford frame for several weeks and a plaster cast then applied. Paralysis and incontinence were complete on admission but slowly disappeared. The Queckenstedt test revealed no spinal block, although spinal fluid was bloody.

lamina, and articular facets—are more rare and some of them difficult to demonstrate even in the x-ray. The clinical manifestations consist of local pain and tenderness, rarely deformity. Prolonged immobilization is the proper form of treatment.

Traumatic spondylitis (Kümmell's disease) is a painful lesion of the spine associated with a definite kyphos (gibbus) and occasionally with manifestations of spinal cord compression. It is presumably due to a compression fracture which had been overlooked or inadequately treated. Treatment consists of prolonged immobilization in a hyperextended position.

Cervical Spine. This part of the vertebral column is more movable and hence more easily dislocated than fractured. The force producing the dislocation may be trivial, such as a sudden twist of the neck, but is usually a severe blow or fall on the head which is transmitted to the spine. The clinical diagnosis of a cervical spine injury is usually easy because of the pain produced on movement of the neck and the abnormal position in which the head is held. Fracture dislocations are common and unfortunately are more serious even than dislocations. Whiplash injuries sustained in automobile accidents are quite common and are often associated with fractures which are usually not diagnosable without x-ray aid (36).

Dislocation of the Articular Facets. The most common lesion is an *unilateral dislocation* of the articular facet, usually of the third, fourth, or fifth vertebra, which is displaced anteriorly over the one beneath (Fig. 37). This is usually evident in the lateral x-ray film because the body of the dislocated vertebra is dislodged forward (Fig. 38). The patient's head is turned away from the dislocated side, the chin elevated, and the head flexed toward the lesion, producing an attitude similar to that in torticollis. Attempts at rotation of the head toward the dislocated articular facet meet a definite block and produce severe pain. When both facets of the vertebra are dislocated, the head and chin are forward and movement to either side is limited and painful. Much more serious are injuries to the first and second cervical vertebrae (atlas and axis), particularly if the odontoid process is fractured, because of the danger of compression of the medulla which

Fig. 37. Characteristic attitude in unilateral dislocation of the articular facets (right) in the cervical spine. This patient, a 21-year-old clerk, gave a history of having his neck manipulated as a therapeutic procedure to relieve a sore throat. X-ray revealed a dislocation of the second on the third cervical vertebra; reduction was easy.

results in immediate death. The disability and pain in fracture or dislocation of the atlas and axis are similar to, but more severe than, injuries to the other cervical vertebrae. Diagnosis depends largely on adequate x-ray films; to show the atlas and axis an anteroposterior view taken through the wide open mouth is essential.

Treatment of dislocations of the lower cervical vertebrae consists of immediate reduction by traction and manipulation. Traction may be readily achieved by means of a halter around the patient's head and a muslin band around the operator's waist; by leaning back, traction is obtained and the hands left free for manipulation. Traction should be maintained for several minutes to overcome muscle resistance (37, 38). The head is slowly rotated toward the side opposite its original displacement. Sudden movements are contraindicated. General anesthesia is necessary to overcome pain and muscle spasm. The reduction is usually evident by a bone click and by the complete mobility produced; it should

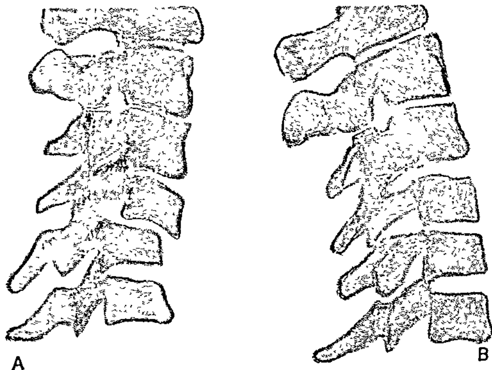

Fig. 38. Marked forward displacement of fourth on fifth cervical vertebra due to a dislocation of the left articular facet. The patient, a 40-year-old chauffeur, could not turn his head to the left and suffered pain and weakness of the left arm and shoulder which disappeared completely after reduction. A, before reduction, and three weeks after an auto collision in which the patient was thrown violently from his car; B, after reduction, while patient was in a plaster cuirass, similar to that illustrated in Figure 39.

Fig. 39. Plaster cuirass for immobilization of the cervical spine. This type of fixation is commonly used for immobilization after reduction of a dislocated cervical vertebra or for a fracture of one of the vertebrae. In six or eight weeks it may be replaced by a collar brace.

be verified by a lateral x-ray film. Immobilization is achieved by a plaster cast (Fig. 39) for a few weeks, after which period a leather or celluloid collar may be substituted. If primary reduction is unsuccessful, open reduction should be undertaken. This procedure, however, should never be attempted except by men experienced in the field. Intubation anesthesia, correct placement of the patient on the operative table, adequate exposure, and accurate hemostasis cannot be left to chance. The treatment of injury of the atlas and axis consists of immobilization in a plaster cast which protects the base of the skull and immobilizes the spine down to the pelvis. Manipulation is avoided to minimize the danger of medullary compression.

Any patient suspected of having a fracture or dislocation of the cervical spine must be transported with great care with the head firmly immobilized; danger of damage to the spinal cord is ever-present until fixation is adequately achieved.

Fracture of the Cervical Vertebrae. These injuries (Fig. 40) are very serious, often resulting in death because of spinal cord damage. Patients with such injuries, or suspected of having such injuries, must be handled with extreme care lest manipulation of the neck cause cord damage by laceration with the bone fragments. Treatment is conservative except in rare instances when there appears to be progressive hemorrhage or penetration of the cord by a fragment of a vertebra. Traction with maintenance of the usual cervical lordosis is the treatment usually utilized. A canvas sling or Crile head halter may be used, thus avoiding any cperative procedure. The latter obtains its traction without any sling around the chin, thus being slightly more comfortable than the canvas sling; its purchase is obtained by pressure of the apparatus against the forehead and occiput. If the head injury involves the chin and forehead, traction can be achieved by the Crutchfield or Barton tongs; each type can be anchored in the outer table of the skull by inserting the prongs in a small drill hole in the bone. The former is anchored in the vertex of the skull and the latter in the parietal bosses. Traction must be maintained for 8 to 12 weeks; however, when the sling or head halter method is utilized, the traction should be released carefully every few days to inspect the pressure points of the bandage for skin damage which is not uncommon with traction of this type.

Ribs. *Fractured ribs* are frequent in any crush injury and, if the patient is conscious and rational, produces characteristically sharp pain on deep respiration. The acts of sneezing and coughing are particularly painful. A history of difficulty in getting in or out of bed because of pain in the neighborhood of the fractured ribs is almost always obtainable. To protect the injured bones from movement, the patient will frequently use only abdominal respiration. Palpation of the individual ribs will nearly always indicate the site of fracture by eliciting the point or points of maximum tenderness. X-ray films may reveal the fracture but, in general, are comparatively unreliable, particularly if there is no displacement and the break is in

Fig. 40. Longitudinal fracture of the body of the fifth cervical vertebra. X-ray reveals displacement of the anterior fragment, and a loss of the normal cervical lordosis. This patient had transient neurological finding of the upper extremity. Cervical traction was used for six weeks followed by a cervical torso cast for three additional months.

the axillary line (unless a lateral or oblique view is also obtained).

Associated with fractured rib, and of much more serious significance, is injury to the underlying lung. The existence of subcutaneous emphysema (a crepitant sensation on light palpation) is suggestive of pulmonary lacerations; the presence of air and blood in the pleural space (pneumothorax and hemothorax) is more conclusive; occasionally hemoptysis occurs. Physical examination will reveal evidence of pneumothorax and hemothorax, but an adequate x-ray is most conclusive of all. The x-ray should be taken in the upright position to show a fluid level, or if that position is inadvisable, an anteroposterior view should be taken with the patient lying on his sound side. The presence of collapsed lung, shifting of the trachea and heart, as well as the demonstration of a fluid level, are of special significance. Clinical manifestations of lung damage may be absent, but such evidence of respiratory difficulty as a rapid rate and cyanosis indicates serious impairment of gaseous interchange and makes treatment more urgent.

In simple fracture of the ribs, *treatment* is directed toward immobilization of the thorax, largely to relieve pain. This is best achieved by a firm circular bandage applied at the time of deep expiration when the chest is collapsed. A chest binder may also be used. Elastic adhesive (elastoplast) applied completely about the chest in expiration is effective and comfortable. Adhesive strips which embrace half the thorax are ineffective. However, adhesive strips placed all the way around, except for about two inches on the side opposite the fracture, will be fairly effective in supplying immobilization and relieving symptoms. Relief of pain and easier respirations should follow the application of an adequate support. Codeine sulphate (0.25 grain or 0.5 grain) should be given every

four to six hours during the painful stage. This treatment is performed even in the face of internal injuries which are insufficient to demand more than rest and conservative care. The operative and other treatment of the injuries to the lung associated with fractured ribs are described in Chapter 36.

Sternum. Fractures of the sternum may be produced by direct blows or crush injuries, but are comparatively rare. Manifestations consist of tenderness over the line of fracture and pain in this area upon deep breathing, coughing, and so forth. The patient prefers to allow the head and shoulders to droop forward, since this position relieves the pain. Since the fracture line can rarely be palpated, any patient complaining of significant pain and tenderness in the region of the sternum should have an x-ray. Usually only the lateral view is of any value. Displacement of fragments should be corrected if possible, but healing with fragments in poor position is rarely accompanied by any permanent difficulty. If pain is considerable, strapping with adhesive may be inadequate and immobilization in bed may be necessary. Contusion of the heart may complicate injuries of the sternum (Beck).

THE SKULL

Although the serious aspects of head injuries are frequently thought of as being produced by fracture of the skull, in reality they are secondary to intracranial injury and increased intracranial pressure. Naturally, fracture of the skull may be accompanied by tenderness along the fracture line, but even this manifestation, which is so consistently present in other fractures, may be absent. Therefore, it may not be possible to make an accurate diagnosis without an x-ray, except through manifestations produced by the intracranial injury. Obviously, bone fragments may actually be visible in compound fractures, and deformity demonstrated in depressed fractures. However, since most of the manifestations and serious effects encountered in fractures of the skull are secondary to intracranial injury we have included the entire subject in the chapter dealing with the nervous system.

THE FACIAL BONES

PAUL W. GREELEY

Principles in the Diagnosis of Fractures. Clinical diagnosis of fractures of the facial bones can be made with a high degree of accuracy (39). An ecchymotic orbit is suggestive of a malar bone fracture. Palpation for irregularities of the orbital floor, flattening and depression of the malar eminence, and subjective complaints of diplopia and numbness along the distribution of the infraorbital nerve make the probability of malar fracture quite certain. A concave depression over the zygomatic arch suggests a depressed fracture in this area. Depression of the bony fragments may press against the underlying coronoid process and make opening of the mouth difficult or impossible. Tenderness along the mandible in one or more areas, together with irregularity of the lower teeth, suggests mandibular fracture. The maxilla may be movable and even found dropping downward into the mouth. Nasal fractures are usually depressed or lateral, depending upon whether the force of injury has been applied from in front or from a blow on one side. Inspection of the nostrils may reveal dislocation of the lower end of the septal cartilage into either nasal airway. The above findings naturally must be confirmed by x-ray studies for obvious reasons.

In the treatment of extensive facial injuries, whether they involve soft tissues or fractures, or both, the establishment and maintenance of an airway is imperative. As stated previously, this may necessitate an emergency tracheostomy as the initial part of the treatment.

Except for certain nasal fractures, endotracheal general anesthesia should be given priority.

Nasal Bones. Nasal fractures can ordinarily be manipulated with the aid of an intranasal elevator or Walsham forceps, using the thumb and index finger of the opposite hand to palpate the external alignment of the nasal arch bones. If the septal cartilage has been dislocated out of its bony groove, it must be manipulated back into position with an Asch forceps. Once reduction has been secured, a piece of vaseline gauze is packed loosely into each nasal airway to maintain

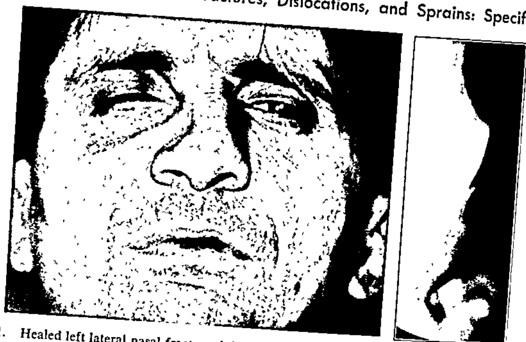

Fig 41. Healed left lateral nasal fracture deformity. Note deflection of nose and adjacent x-ray which reveals a typical fracture.

Fig. 42. Schematic anatomic drawing to show method of insertion of elevator into antrum to elevate depressed malar bone fracture.

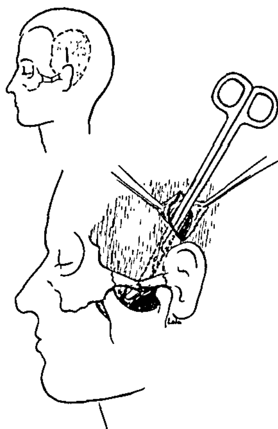

Fig. 43. Gillies' method of elevating depressed fractures of the zygomatic arch. An incision through a shaved area in the temporal region is made through the skin and temporal fascia. An elevator is then passed between the temporal fascia and temporal muscle until it comes to lie beneath the zygomatic arch fracture. The depressed fragment can then be manipulated upward into normal position.

position of the fragments in normal alignment. External fixation is rarely indicated. The vaseline packs are removed in two to four days.

If early reduction of the bony and septal segments is not carried out, they will heal in malposition (Fig. 41). This will necessitate a more complicated procedure of open reduction and sometimes submucous resection at a later date.

It is easy to overlook a nasal fracture in a small child. A minor displacement at this age frequently damages the epiphysis. This in turn will cause the nose to become distorted as growth and development follow.

The Zygoma (Malar Bone). Simple or comminuted depressed fractures of the malar bone can be elevated through the transantral approach. A small incision is made in the upper buccal sulcus. An elevator is then slipped into the antrum, beneath the malar bone (Fig. 42). The fragments are then lifted or molded upward into normal anatomic position. An iodoform gauze pack is then left in the antrum beneath the malar to hold it in position until early union occurs. The pack may be removed in seven to ten days.

Fractures of the zygomatic arch are reduced by the method originally described by Gillies (40) (Fig. 43). Once reduced, the fragments will stay in position without other fixation because of the arched shape of the bone.

The Maxilla (Upper Jaw). Complicated fractures of the maxilla and mandible present more difficult methods of therapy. We are very much opposed to the use of any type of traction apparatus applied from a plaster of paris head cap. We feel that this gear is uncomfortable to the patient; it may produce pressure necrosis of the scalp and forehead skin; and, in many instances, it fails to reduce the fracture. Traction-suspension apparatus with the patient in bed for several weeks has no practical place in present-day management of maxilla fractures. Likewise, the use of external pin fixation in the treatment of mandibular fractures must be considered archaic. Pin sequestra, infection, and severe postoperative pinhole scars are inevitable.

As an alternative, we prefer to treat complicated facial bone fractures as one would do with a complicated fracture of the tibia or femur, i.e., by open reduction. Properly executed, the reduction and fixation can be made accurate, and complicating infection is negligible. Furthermore, it is a very comfortable method for the patient and ordinarily involves but a few days' hospitalization (Figs. 44, 45).

Fractures Through the Central Third of the Face. These fractures are usually accompanied by a downward displacement or "floating" of the maxilla (Fig. 44). The maxilla should be lifted into normal position and held there by an assistant. A Kirschner wire is then driven through a fixed point of the malar-zygomatic compound on one side and a similar one from the opposite side (Fig. 45). The Kirschner wires are clipped off just

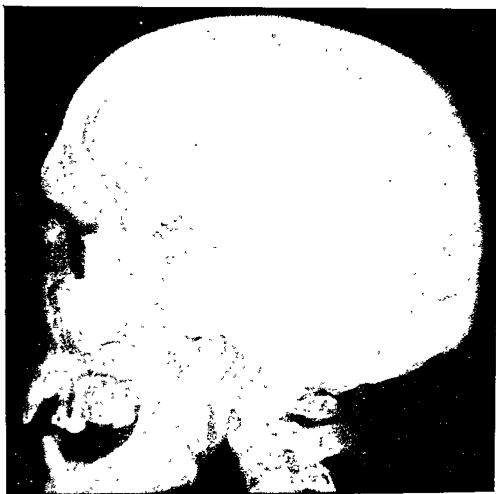

Fig. 44. Fracture of the facial bones. The nasal bony arch and maxilla have been displaced forward and downward. There is also a fracture of the mandible which does not show on this view.

beneath the skin. This fixation holds the maxilla in excellent position in a comfortable manner for the patient. The wires are removed in approximately eight weeks.

The Mandible. The management of uncomplicated fractures of the mandible can ordinarily be handled by simple interdental wiring, with or without elastic traction, as indicated. Fractures of the alveolar ridge can usually be maintained in good position with an arch bar secured to the teeth. Fractures of the condylar head or condylar process do not ordinarily need any special attention unless they are displaced in such a manner that normal temporomandibular joint function is impaired. Open reduction in these instances is not ordinarily as successful as complete removal of the displaced fragment. Temporary interdental wiring for two to three weeks may add to the patient's comfort.

Sometimes one is confronted with a tooth in the line of a mandibular fracture. If left in position, the tooth is apt to provide a direct communication from the oral cavity into the fracture site. This may lead to infection; hence such a tooth is frequently removed.

Complicated and multiple mandibular fractures and those in edentulous patients are exposed through small external incisions. The bone ends are secured by direct wiring with stainless steel through small drill holes placed near the fracture site (Fig. 45). If fractures of the mandible are neglected, nonunion and osteomyelitis are apt to result (Fig. 46).

Dislocation of the Jaw. Dislocation of the jaw is a relatively uncommon injury; the condyles are usually displaced forward, i.e., anteriorly. The mouth is held open. Pain is moderate and talking or chewing difficult, if

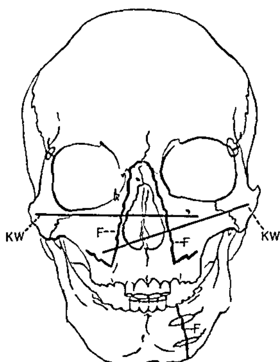

Fig. 45. Fracture after reduction and fixation. Same patient as in Figure 44. The central third bony structures (superior maxilla and nasal bony arch) have been reduced to normal position and secured by two Kirschner wires. Mandible fragments held by two stainless steel wire loops placed through drill holes. F indicates fractures, and KW indicates Kirschner wires.

not impossible. Reduction is effected by placing the thumbs in the mouth on the lower molars and depressing the mandible downward while it is at the same time being pushed posteriorly. (The operator should always protect his thumbs by wrapping a towel around them. Failure to do this may cause a crushing injury to the thumbs when the mandible snaps back into normal position). Reduction may be attempted without anesthesia; but anesthesia of some type, preferably ether or pentothal, is usually necessary. The patient should be instructed not to open the mouth very widely for two or three weeks after reduction, since dislocation might easily recur by such a simple mechanism as yawning.

Repeated mild dislocation of the temporomandibular joint is a frequent cause of chronic pain for which many patients seek relief. Often they complain also of an annoying click whenever the jaw is used. Relief may often be obtained by using only the molar teeth for chewing and avoiding the use of the incisors for biting. Although operative therapy has been used for the severe cases, Schultz has described a simple method by which a fibrosis and shortening of the joint capsule is achieved by the intraarticular injection of a solution of sodium psylliate.

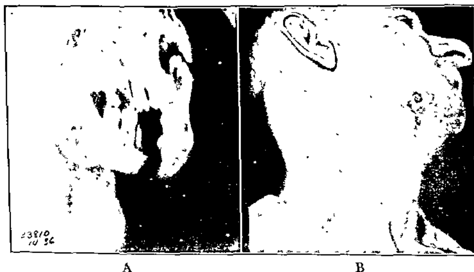

Fig. 46 Untreated fracture of mandible. A, x-ray at time of admission, five weeks after injury; note separation of fragments. B, patient developed an abscess which ruptured spontaneously with the formation of a sinus as noted in the photograph. An osteomyelitis is now present.

THE ORGANS OF MOVEMENT

PHILIP D. WILSON

The organs of movement include bones, joints, bursas, tendons, and muscles, and diseases affecting them are commonly the cause of serious disability. This is true not only because they are subject to frequent injury and infection and are involved in systemic disease, but also because of their dense rigid structure and relatively poor blood supply, particularly bones and joints; this last factor probably accounts for their slow and often imperfect power to overcome the effects of disease. Of special importance, too, is the tendency for bone, joint, and muscle to suffer from serious disability through rest or disuse. Since immobilization is an important aid in treatment, particularly of injuries and infections, it is obvious that such deletorious changes are to be prevented if possible. The term *atrophy of disuse* is used to describe the changes which follow prolonged immobilization (Fig. 1). These changes include atrophy of muscles, decalcification of bone, and stiffness and even fibrous ankylosis of joints. They begin very soon, but are apparent only after a few weeks, and become pronounced after months. Care should be taken in each case to utilize only a sufficient period of rest to allow healing without inducing atrophy of tissues. This is often a difficult problem because the healing of bone and joint injuries, and especially infection, frequently requires many weeks and months and sometimes years. Though the organs of movement, per se, are not vital structures and are not often the seat of diseases which endanger life, they play an important part in our socio-economic structure. Diseases of these organs are frequent causes of loss of time in industry and constitute the main basis for workmen's compensation laws. They, therefore, have a great medicolegal importance.

Many of the diseases discussed in this chapter "belong" to the field of orthopedic surgery and are therefore considered only in basic and general terms. Detailed descriptions may be found in textbooks on orthopedic surgery, particularly those of Howarth (1), Luck (2), Ferguson (3), Ropes (4), Campbell (5), and Mercer (6). Of the various lesions which affect the organs of movement, fractures are described in separate chapters. The others are classified in terms of the specific tissue involved.

BONE

Bone is subject to trauma, neoplasm, and infection and is the site of constitutional diseases and congenital deformities. Only the last two groups are described herein; the first and second have been discussed in preceding chapters.

Pyogenic Osteomyelitis. Modern chemotherapy, as discussed in a separate chapter, has revolutionized the clinical diagnosis and course of acute osteomyelitis, as described especially in Chap. 5 (Figs. 2, 3). To a considerable extent, therefore, the following details (except for the early clinical picture) are largely of historical interest. However, it is likely that more of the original later manifestations of these infections may be seen in the future as more of the organisms, espe-

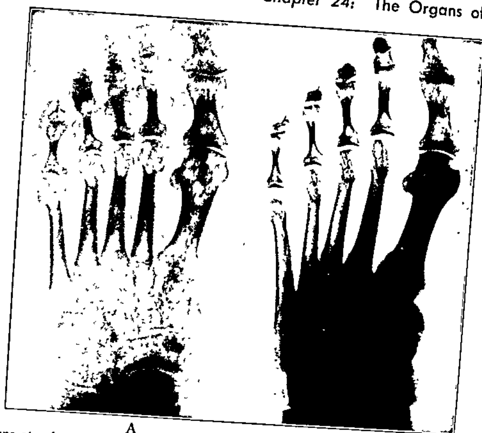

Fig. 1. Bone atrophy. A, bone atrophy revealing extreme decalcification in the foot of a 48-year-old man after prolonged immobilization because of an infected compound fracture of the leg; B, a normal foot of a man of the same age for comparison.

Fig. 2. Acute osteomyelitis of the tibia. Lateral and anteroposterior radiologic views show early, barely detectable changes. The changes in density are slight but can be seen just above the epiphyseal line. The disease started apparently five days previously. It is unusual for roentgenologic changes to occur this early. Operation was performed a few hours after admission. A huge subperiosteal abscess was encountered; a large amount of pus was also present in the medullary cavity. Adequate drainage was instituted and a plaster cast was applied. Extensive destruction of bone had already taken place at the time of operation; this is apparent from the bone involvement which ultimately showed up in the x-ray (see Fig. 6). Staphylococcus was the causative organism. Chemotherapy even if started at the time of admission would have prevented the subsequent course (See Chap. 5).

Fig. 3. Acute osteomyelitis of the tibia. Roentgenograms shown above were obtained from a six-year-old girl, who entered St. Louis Children's Hospital six days after the onset of pain in the left leg followed by fever and rapidly increasing prostration. On admission she was almost moribund, with signs of overwhelming infection, temperature 41° C. (106° F.), uncountable pulse and rapid respirations; the lips and finger tips were cyanotic. The entire left leg was tremendously swollen and red. Supportive therapy and penicillin injections were carried out. The general condition improved. In a week simple incisions of the skin of the leg yielded a large amount of pus from the subcutaneous tissues, from which a pure culture of *Staphylococcus aureus* was grown, the same organism as was obtained from the blood. X-ray at this time (a) was negative. Improvement was slow but continuous. Two weeks later or four weeks after onset the x-ray (b) showed changes for the first time, which involved the entire shaft. Improvement continued and the patient went home in a cast over the draining wounds. Four months after onset, x-ray (c) revealed a spontaneous fracture. Dead bone could be seen in the wound and a simple sequestrectomy was therefore carried out. The wound discharged small bits of bone spontaneously thereafter, but eventually healed. The x-ray (d) was obtained seven months after onset and shows satisfactory progress. The x-ray (e), 18 months after onset, shows *complete solidification. The patient attends school and has little if any deformity* or disability aside from the scars on her leg and has had no recurrence. *Note* that several weeks passed before roentgenologic changes were visible in the bone. Note also the extensive changes in the upper part of the tibia shown in (b) which gradually disappeared without operative interference. Without penicillin this patient would probably have succumbed to the systemic effects of the severe infection, or, if she had recovered, complete sequestrectomy of the entire shaft would have been eventually necessary. Had penicillin been started earlier the extent of bone involvement would have been greatly reduced or even entirely eliminated.

cially the staphylococcus, are becoming insensitive to penicillin and other antibiotics. Moreover, neglected disease, even in spite of progress in chemotherapy, is still being seen, especially in certain parts of the world not blessed with all the good things of life, including antibiotics. Pyogenic osteomyelitis may be considered in three groups: 1. acute primary, 2. secondary, and 3. chronic osteomyelitis.

1. *Acute Primary Osteomyelitis.* As a primary infection, acute osteomyelitis is not un-

Fig. 4. Neglected acute osteomyelitis. The patient, a 12-year-old girl, was treated as a case of "rheumatism" for four weeks before admission. X-ray showed involvement of the entire shaft of the tibia. As can be seen from the photograph, the leg was literally a "bag of pus"; this was confirmed at operation when a large quantity of staphylococcus pus was evacuated.

common in childhood but is rare in adult life. It is a hematogenous infection of bone due to the staphylococcus (Fig. 4), occasionally the streptococcus which is considered separately. Not infrequently the infection seems to arise from some obvious pre-existing lesion—such as a furuncle, septicemia, otitis media—but more commonly through some occult or unknown portal of entry. Accordingly there is always a bacteremia, and often a septicemia, present before the osteomyelitis develops. There is frequently a history of injury at the site of the infection, but its etiological importance is unestablished. The organisms lodge in the marrow cavity of the metaphysis, presumably because the terminal capillary loops at the epiphyseal line empty into large venous sinuses where the blood current is slowed sufficiently to allow the bacteria to gain a foothold and multiply. The resulting acute inflammatory reaction being in the closed bony structure develops extreme pressure and causes intense pain and disability. The infection spreads by direct extension. It rarely if ever breaks through the epiphyseal line into the epiphysis, but it penetrates the cortex through the Haversian canals, a process which usually takes a number of days. In any case, pus finds itself under the periosteum which it strips away from the bone, thus forming a subperio-teal abscess which sooner or later ruptures into the overlying soft tissue and ultimately forms a subcutaneous abscess. Of greatest significance in this process is the actual amount of bone infected and killed by the disease. This is not apparent until later, but it determines the further course of events. In the severe cases the entire shaft may become necrotic. On the other hand, the infection may break through the cortex so soon (or with the aid of the surgeon's drill) that very little bone is killed (Fig. 5). Although the infection rarely penetrates the epiphyseal line, pyogenic arthritis may occur after pus has appeared under the periosteum and extended from this point into the joint.

Reparative processes begin first by the separation and partial phagocytosis of necrotic bone which becomes demarcated from the viable cortex and is called a *sequestrum*. Secondly, nature begins to build new bone to take the place of that destroyed by the infection. Osteogenesis occurs from the lifted up periosteum and probably begins early, although it cannot be seen roentgenologically for two or three weeks. The new bone is called *involucrum;* it eventually becomes dense, hard, and rich in calcium, and replaces the necrotic bone. It develops in the presence of the sequestrum and even while the tissue is bathed in pus, regardless of whether treatment has been instituted or not. On rare occasions the infection does not extend or penetrate, but forms a localized lesion in bone, called *Brodie's abscess,* which ordinarily develops insidiously and is really a manifestation of chronic osteomyelitis. From the primary bone lesion, metastatic foci may develop. It is not uncommon for several bones to become infected one after the other. In a few unfortunate children this succession would continue for years so that eventually most of the long bones became the site of osteomyelitis. The bones commonly in-

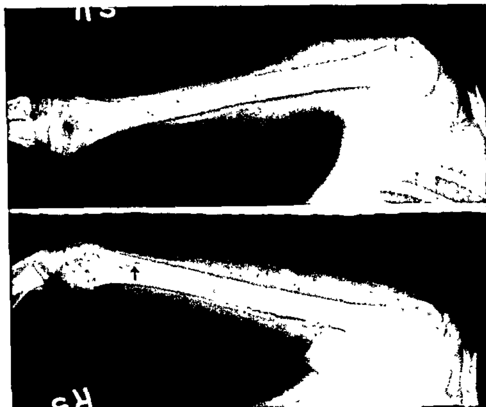

Fig. 5. Acute osteomyelitis of the humerus in a girl ten years of age; the anteroposterior and lateral roentgenograms were taken three weeks after onset. The arrow points to some of the decalcified areas of the osteomyelitis. Involucrum has already developed and may be seen on each side of the shaft. (Courtesy, Dr. Robert Ray.)

volved, in order of their frequency, were tibia, femur, humerus, radius, ulna, fibula, and the metatarsal bones. Abnormal lengthening of the affected bone occurred in many children after many months, apparently due to the increased blood supply, the hyperemia at the epiphyseal line augmenting local bone growth (Trueta). When the epiphyseal plate was destroyed, shortening of the limb resulted.

Clinical manifestations are systemic and local. The former are those of general septicemia and include fever, chill, leukocytosis, rapid pulse, and prostration. The severity of the systemic manifestations vary with the virulence of the organism. In adults, the general reaction is apt to be less severe; subacute and chronic forms are more frequently encountered in which the infection develops slowly. The local signs and symptoms in the typical acute case are those of a deep-seated infection. The pain is severe and located over the end of the bone close to the joint. While muscle spasm is present to a slight extent, the joint can be moved somewhat without increasing the pain. Acute tenderness over the involved bone on deep palpation is one of the earliest signs. In eliciting this tenderness the bone is carefully palpated, starting at some distance from the lesion which is approached gently and gradually in a manner similar to that used in the detection of point tenderness over a fracture. The overlying tissues may be swollen and edematous, but the skin itself is not red or tender during the early stage of the disease. If the infection has been present for several days there may be evidence of a local abscess, i.e., swelling, redness, local heat, and fluctuation.

Streptococcal osteomyelitis differs considerably from osteomyelitis produced by the staphylococcus. The former much more commonly occurs as a metastatic invasion of the bone from a primary source—such as otitis media and mastoiditis. The manifestations of the streptococcal osteomyelitis are apt to develop more insidiously than the staphylococcal infection. The pain is not so severe;

swelling and subcutaneous suppuration develop more slowly and less commonly. There is less destruction of bone; sequestration is therefore less marked. Many such lesions will subside without gross suppuration when properly treated with antibiotics. They are particularly prone to occur in infants under two years of age.

Diagnosis, though more difficult when the patient is seen early, should be made as soon as possible, because of the need for prompt treatment. The diseases which may be confusing are acute rheumatic fever, acute pyogenic arthritis, and acute cellulitis; the differential diagnosis is discussed on page 544. X-ray is disappointing because the earliest roentgenologic evidence of acute osetomyelitis is absorption of bone which ordinarily is not demonstrable for a week or more following the onset. Involucrum formation is seen when new bone becomes deposited under the elevated periosteum and requires at least two weeks. Sequestration may not be demonstrable for an even longer period. The local signs and symptoms are, therefore, of greatest importance and should be carefully noted; and examination should be repeated at short intervals if necessary.

The *treatment* of staphylococcal osteomyelitis was revolutionized by the introduction of penicillin therapy. If the patient is seen within a day or two of the onset of the infection, i.e., before necrosis of bone has occurred, chemotherapy will permit healing without operation. Even if there is evidence of suppuration, operation may often be avoided even if it is against the principle that the presence of pus requires incision and drainage, regardless of the influence of chemotherapy. For example, Altemeier and Helmsworth (7) presented evidence of excellent results following penicillin therapy in which operation was postponed indefinitely and used later only when spontaneous drainage appeared inevitable or a well-developed sequestrum was demonstrable. Even in the days before chemotherapy, operation in acute osteomyelitis was not an extensive procedure and consisted merely of drainage of pus by incising the periosteum and, in many instances, placing a simple drill hole into the metaphysis close to the epiphyseal line, which, however, could not be injured because of the danger of growth disturbance. On the other hand, if the hole were drilled too far from the epiphyseal line the metaphysis would be missed, or still worse the open medullary cavity of the diaphysis would be entered with danger of spreading of the infection to the entire shaft. At most, the bone between such openings was removed to permit more ready drainage, but extensive resection of the cortex was unnecessary and deleterious. The wound was left open. Later petrolatum packs containing tubes were inserted for the local instillation of penicillin solution. Frequent dressing was condemned because it was painful and deleterious. Orr (1927) popularized the idea of immobilization of the extremity in a plaster cast. The effectiveness of this method was established by much clinical experience. Such a cast, left in place for three or four weeks, obviated the need for dressings and produced complete rest and alleviation of the local pain. An excellent study of acute osteomyelitis before the days of chemotherapy is that of Miller (8).

As already suggested, the treatment of streptococcal osteomyelitis even before chemotherapy was often nonoperative. Surgical procedures were delayed even when a localized destruction of bone was observed in the x-ray. Incision of superficial abscesses as they developed was obviously indicated. The introduction of chemotherapy has added further justification for this attitude.

2. *Secondary Osteomyelitis.* This term is used to describe a variety of bone infections in which the infection arises, not in the bone itself but elsewhere, and involves the bone secondarily, usually by direct extension. A common type is that which may follow compound, or open, fractures. Secondary osteomyelitis of the jaw often develops by extension from a cellulitis about a tooth. If the tooth is pulled at the improper time, osteomyelitis is particularly prone to develop and may lead to severe systemic manifestations. The terminal phalanx becomes the site of osteomyelitis following a neglected felon. The other phalanges are frequently infected secondarily from acute suppurative tenosynovitis. Osteomyelitis of the tarsus is sometimes secondary to penetrating infections and may eventually involve the entire foot. Am-

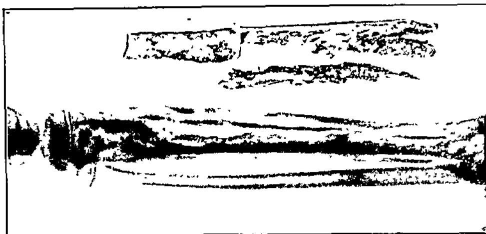

Fig. 6. Chronic osteomyelitis. The patient was a six-year-old boy. The early stage in this patient is presented in Chapter 24, Figure 2. The x-ray film illustrated was taken three months after the first operation and just before sequestrectomy. A photograph of a portion of the sequestra which were removed is also shown. A cast was reapplied; two months later the wound was almost completely healed by granulation.

putation is often necessary as a last resort. The patella and olecranon are sometimes involved by direct extension from an overlying lesion. Osteomyelitis of the skull is secondary to compound fracture, neglected sinusitis or avulsion of the scalp. Osteomyelitis is always suspected when an abscess or infected wound located near bone fails to heal and forms a chronic draining sinus. X-ray may enable one to make a definite diagnosis. During the acute stage, treatment is that of the primary lesion.

Treatment of secondary osteomyelitis depends on the nature of the primary lesion and the bone affected. Although most types heal readily, the osteomyelitis following compound fractures has always presented a choice of nonoperative versus operative therapy. The problem is somewhat similar to that in chronic osteomyelitis which follows a primary infection of bone and is discussed in more detail under the next heading.

3. *Chronic Osteomyelitis.* This lesion is the outcome of acute or secondary osteomyelitis which has resulted in necrosis of bone (Fig. 6). Its severity depends on the extent of bone killed by the infection which, as already stated, is influenced to a large extent by the promptness of chemotherapy and/or operation in the acute stage of the primary disease. An extremity which is the site of chronic osteomyelitis shows considerable muscular and bone atrophy and exhibits one or more draining sinuses leading to diseased bone (Fig. 7). X-ray will reveal the extent of the lesion and often will clearly demonstrate the site and size of sequestra.

Treatment of chronic osteomyelitis following an acute primary osteomyelitis in its early stages is, to a large extent, nonoperative. When the infection involves a long bone of an extremity, protection of the limb is important to avoid the danger of fracture before a strong involucrum forms. This, indeed, is all that need be done in most patients. Small sequestra are often discharged from time to time or are absorbed. However, as long as dead bone remains, it acts as a foreign body and permanent closure of the sinus will not occur. With adequate chemotherapy the sequestrum may become revascularized, act as a bone graft, and become incorporated into the living bone, particularly if the pus surrounding it is absorbed or evacuated aseptically and without producing secondary infection. Operation for removal of sequestra may be carried out as soon as there is roentgenologic evidence that separation between the dead and living bone is well under way and that there is a well-developed involucrum. Operation may also be necessary to drain abscesses or cavities which have formed since the initial osteotomy, or as a primary manifestation (Brodie's abscess). Such operations, however, should rarely be extensive

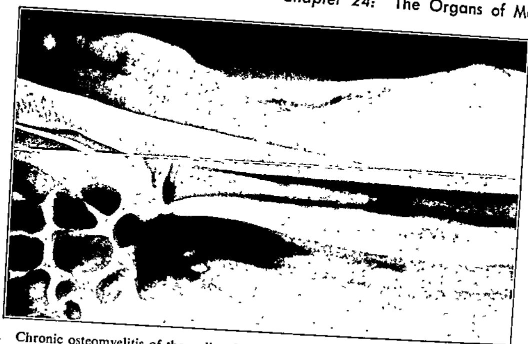

Fig. 7. Chronic osteomyelitis of the radius. The patient was an eight-year-old boy. An operation for the acute infection was performed 10 days after onset; x-ray was entirely negative at this time. The wound discharged small sequestra from time to time, and one large one was removed operatively, represented by the bone defect in the x-ray. The photo represents the almost healed incision, the radiograph, the end result of bone repair; both were taken nine months after onset. The patient has full use of the arm and atrophy has completely disappeared.

except when the dead bone to be removed involves nearly all of the diaphysis. Healthy bone is resected only to remove loose sequestra or to open and drain residual abscesses; saucerization to eliminate dead spaces is, however, justified. Wounds are left wide open, packed with petrolatum gauze, and a plaster cast applied.

The great difficulty with the conservative treatment of chronic osteomyelitis as just presented was the long period of disability it produced, due to the fact that chronic sinuses failed to heal. Radical operation for the removal of dead tissue and elimination of dead space has been greatly stimulated by the introduction of chemotherapy. At first it was thought that penicillin or other antibiotics alone would permit these wounds to heal. This hope was not fulfilled due undoubtedly to two factors; first, the presence of mixed infection, and second, the existence of necrotic tissue in the wound, into which penicillin could not penetrate. However, with chemotherapy, earlier operations are now safe and effective, even permitting primary enclosure with a high incidence of primary healing. In this way, months have been saved in the treatment. With the aid of chemotherapy, the fear of spread of infection, which occasionally followed any attempt at surgical closure, has been greatly reduced.

The experience in World War II with chronically infected compound fractures has also shown the great value of chemotherapy in association with properly timed and adequate operation. This included the use of skin grafts over large granulating areas as well as extensive excision of nonviable or chronically infected tissue and obliteration of cavities. In many cases, chronic osteomyelitis following fracture has even been prevented by closing contaminated wounds relatively soon after injury (delayed closure). The primary healing thus achieved saves countless months of disability.

Tuberculosis of Bone. The distinction between tuberculosis of the bone and of the joint is not always clear since the tubercle bacillus often seems to attack both structures together (see p. 546). In the *spine* (Pott's disease) (Fig. 8), it starts in the vertebral body, destroying it and the associated intervertebral disc, producing a deformity (gibbus, kyphosis). Usually a cold abscess is formed which, in tuberculosis of the lumbar spine, may burrow along the psoas muscle

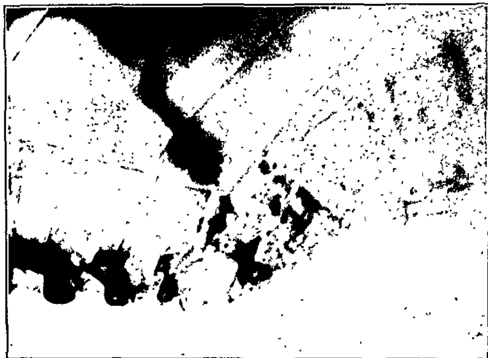

Fig. 8. Tuberculosis of the spine (Pott's disease). The patient was a 13-year-old girl. The roentgenogram reproduced above is a lateral view and shows the destruction of the bodies of the eleventh and twelfth vertebrae, and the marked angulation. However, no signs of spinal cord pressure were present. The disease started six years previously with a reputed injury followed by persistent pain in the back. The child's complaints were minimized until an x-ray revealed the true diagnosis six months later. Following the unsuccessful use of more conservative measures spine fusion was performed. This operation is an ankylosing procedure which immobilizes the spine by creating a bony arthrodesis between the lamina, the articular facets, and also between the dorsal spines. (Courtesy, Dr. F. A. Jostes.)

and present in the groin as a psoas abscess. It does this so silently that the fluctuant inguinal mass may be mistaken for a hernia. The cervical spine is also involved and may be associated with a cold abscess of the neck. Occasionally abscess or tuberculous granulation tissue invades the spinal canal and, in association with the kyphosis, produces pressure on the cord, and a spastic paralysis ensues. The head of the *femur* is also frequently involved, especially in children, but the clinical manifestations are so distinctly referable to the joint that it will be included under joint disease. Another favorite site of bone tuberculosis, in Negroes at least, is the sternal end of the *clavicle*.

Tuberculosis of bone heals by fibrous replacement or by ankylosis when joints are involved. The disease responds slowly to treatment, which is largely an orthopedic problem and consists of *immobilization, nutritional care*, and chemotherapy It should be emphasized that, as a rule, healing is best achieved by ankylosis of the adjacent joint surfaces involved. (See also under Tuberculosis of the Joints.)

Syphilis of Bone. Three types of disease are recognized, although now increasingly rare due to the wide use of chemotherapy: 1. Syphilitic periostitis (Fig. 9) consists merely of a thickening of the periosteum with a roughening of the bone and is commonly seen in the tibia. Local pain and tenderness, especially at night, are complained of in syphilitic periostitis and the x-ray may show characteristic changes. 2. A hyperplastic form occurs commonly in the sternum and the sternal end of the clavicle or the clavicle itself, simulating tuberculosis, particularly in Negroes in whom the two diseases are common. It also occurs in the shafts of long bones as a hypertrophy of the cortex and may simulate *Paget's disease*. 3. A destructive form (gumma of bone) is seen in the shaft of long bones

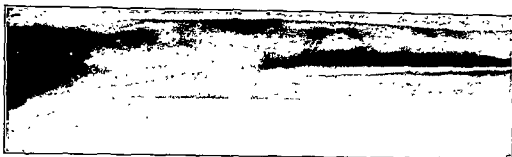

Fig. 9. Syphilitic periostitis in the tibia. Note the surface irregularity, particularly in the proximal portion of the bone. The patient, a 43-year-old woman, had pains in the legs and also had luetic ulcers.

and in the skull. In the x-ray it may simulate primary bone tumor, metastatic carcinoma, or pyogenic osteomyelitis. Diagnosis of bone syphilis is aided by the x-ray and particularly by the finding of a positive Wassermann. Treatment is medical.

Miscellaneous Diseases. These comprise the following:

1. *Rickets* (Fig. 10) is less common than formerly and has a surgical interest only in that it causes deformities in the long bones, especially "bowlegs" and "knock-knees." If the deformities persist in spite of medical treatment, osteotomies may have to be done to correct them.

2. *Osteochondritis deformans juvenilis* (Legg-Calvé-Perthes disease, coxa plana) is a disease of the capital femoral epiphysis affecting children between five and ten years of age and in the past was often confused with tuberculosis. Pain is slight, a limp is followed by atrophy and x-ray shows a progressive flattening and fragmentation of the head of the femur, which is characteristic of the disease. Treatment consists of avoidance of weight-bearing with crutches and an elevated shoe on the unaffected side. A similar lesion has been described in the tibial tubercle (Osgood-Schlatter disease) and in the tarsal scaphoid (Köhler's disease). Diagnosis is made by x-ray. Treatment consists of immobilization when pain is present.

Fig. 10. Bow legs due to rickets. Prevention of this as well as other bony deformities due to rickets is largely a pediatric and orthopedic problem. Osteotomy for correction of deformity as depicted above is carried out only after healing of the active disease has been achieved.

3. *Scurvy,* now a rare disease, is due to vitamin C deficiency and is manifested by bleeding from the gums, tenderness, and swelling of the bones about the joints. Subperiosteal hemorrhage is common and in many instances is a source of the pain. The roentgenogram is characteristic. Treatment is dietetic.

4. *Osteomalacia* is probably also due to dietary deficiencies. It is observed mostly in women. The bones become soft, lose much of their content of calcium, and are subject to fracture and deformities. Pain and stiffness are noted. Treatment is symptomatic and dietetic (vitamin D).

5. *Paget's disease* (osteitis deformans) is characterized by enlargement and distortion of bones, by pain in the limbs, by a decrease in the height, and by an increase in the size of the head (Fig. 11). The condition is uncommon. It has a long course and begins insidiously during middle life; the changes in the skeleton are usually general but are occasionally confined to a few bones, notably the skull and legs. Roentgenograms are characteristic in the osteoblastic phase and show coarse trabeculations, thickening of the cor-

Fig. 11. Paget's disease of the bone. The disease was of slow, almost imperceptible development. The photographs show a well-advanced disease in a 70-year-old male. Note how relatively long the arms are; this is due to an actual shortening of the skeleton produced by a collapse of a vertebra and a bowing of the long bones of the lower extremities. The characteristic x-ray appearance of the disease may be observed in the roentgenograms of the lower leg; note the bowing and overgrowth of the cortex, which, however, is composed of soft osteoid tissue and not true bone. (Courtesy, Dr. W. B. Gnagi, Jr.)

tex, and a loss of the clear delineation between the cortex and medullary canal. In the *osteoblastic* phase, the alkaline phosphatase is markedly elevated. In the osteolytic phase, the x-rays show destruction of bone and the alkaline phosphatase is normal. The tibias are much thicker than normal and bowed anteriorly. The vertebrae are also compressed, apparently from the weight of the body. Spontaneous fractures sometimes occur at the junction of normal and abnormal bone. *Malignant* changes do occur in the form of osteogenic sarcoma. The etiology is unknown and the treatment is merely palliative.

6. *Fragilitas ossium* (brittle bones, osteopsathyrosis, osteogenesis imperfecta) is a rare disease of bones manifested by the presence of multiple fractures after slight trauma. It may be present soon after birth and persist into, or be noted first, in childhood. Many cases are associated with blue scleras. The etiology is obscure. There is no treatment except protection of the extremities to avoid trauma. Spontaneous cure often occurs with the advent of adolescence.

7. *Achondroplasia* (dyschondroplasia) is a rare, deforming disease of the shafts of bone which softens and shortens them due to the formation of osteoid tissue which has little calcium and contains cartilage.

8. *Chondroplasia foetalis* is apparent at birth and is a complex disturbance of bone formation which causes dwarfism, deformities, and a square, large head.

9. Although the muscle paralysis resulting from *poliomyelitis* constitutes perhaps the most serious complication of the disease (except mortality) *bone shortening* takes place and may be sufficient to prevent restoration of proper function even though muscular deficiencies have been corrected. To combat *the disability incident* to the shortening, Abbott (9) has devised a very ingenious method

of lengthening the bones of the leg by operative means. This method is used only in selected cases for it has inherent many complications. *In the great majority of lower extremity length discrepancies, the normal side is shortened.* Before growth is complete, epiphysiodesis or stapling of the normal epiphysis may be done to secure equal leg lengths by the end of the growth period. Obviously this method could be utilized for bone shortening resulting from various causes (see also Wilson and Thompson, Ann. Surg., 110: 992, 1939). Bone shortening is also used to permit nerve suture in the presence of a marked defect in nerve length.

JOINTS

The anatomical structures involved in joint disease consist of the articular (cartilaginous) joint surfaces and the synovial membrane which is a continuation of the cartilaginous layer forming a closed (joint) *cavity. The synovial membrane is composed* of modified fibrous tissue cells or mesothelium which secretes mucilaginous fluid, thereby lubricating the joint surface. It is reinforced on the outside by a supporting layer of dense fibrous tissue called the *joint capsule*. Outside the joint are the ligaments, tendons, and muscles which are attached to the bone on either side and which are more important than the capsule in lending stability to the joint. In some joints there are additional structures—such as the semilunar cartilages and cruciate ligaments of the knee and the round ligament of the hip—which also help in the proper function of the joint.

Traumatic Joint Disease. The synovial fluid has recently been studied extensively by Ropes and Bauer (4). The changes in cell count, viscosity, protein (albumin and globulin), and glucose have been correlated with various pathological conditions in the joint. The reader is referred to this excellent monograph. Injury to joints alone, aside from dislocation, is probably rare because the associated structures—such as tendons, ligaments, muscles, and bone—are nearly always involved in trauma of any consequence. Thorough examination is therefore important in order to arrive at a correct anatomic diagnosis. Acute traumatic arthritis is a collective term applied to various injuries which are described separately below.

1. *Acute Traumatic Synovitis.* This lesion is descriptive of the reaction of the joint itself to injury and consists of the development of *swelling, pain, limitation of motion, and muscular spasm* (Fig. 12). The same reaction occurs to a lesser extent when normal joints, immobilized for many weeks, are first used, especially if the alignment of an associated fracture has been faulty or other structural defects are still present. The same signs are seen in the early hours of an infection. Fluid in the joint cavity (hydrops, hydroarthrosis) is one of the first signs of synovitis and is manifested clinically in the superficial *joints by swelling, by obliteration of the normal bony landmarks*, and by a sense of fluctuation on palpation. In the knee, the fluid lifts the patella from its normal contact with the femur (floating patella) which can often be shown by pressing it against the femur, producing an audible or palpable click. In the hip and shoulder these signs may be obscured by the overlying muscle; comparison with the opposite side may be helpful.

Aspiration of the joint is the surest and sometimes the only way of detecting fluid in the synovial cavity and also reveals the kind of fluid present. If it is blood, proof of hemorrhage is obtained. Investigation of the fluid microscopically and bacteriologically is often useful and important. Removal of blood decreases the danger of limitation of motion from incomplete absorption and organization of blood clots. Aspiration of fluid may also *serve a therapeutic purpose* in relieving the pain and swelling. Pain, however (in the absence of fracture or sprain), is not apt to be severe. When pain is intense, there is usually an associated lesion of bone, ligament, or tendon which is ordinarily detectable by local tenderness. Limitation of motion is usually due to pain and associated *muscle spasm*, but it is also due in part to fluid in the joint. Muscle spasm is a protective reaction which serves to splint the injured part and is prominent in many joint diseases, both acute and chronic. It is sometimes elicited only on movement.

Injuries to bone and cartilage must be excluded before definitive therapy since they

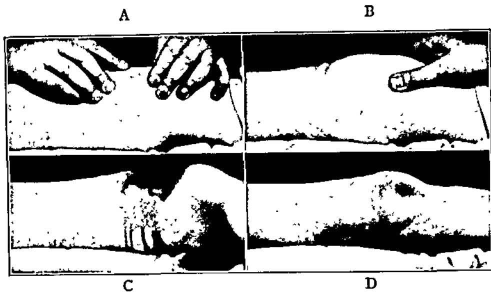

Fig. 12. Acute traumatic synovitis. The patient, a 70-year-old man, was struck by a motorcycle. A, the method of demonstrating a patellar click; the index finger of the right hand presses the "floating patella" against the femur. B, note the obliteration of the normal bony landmarks of the knee joint by the fluid contained within the joint; the examining fingers detect a definite sense of fluctuation. C, aspiration of the joint; nearly 100 ml. of bloody fluid was obtained. The blood pointed to joint damage and an x-ray revealed a tiny but definite fracture into the joint without displacement. D, after aspiration; note the normal contour of the knee.

may demand special treatment. The key to the spontaneous recovery of simple acute traumatic synovitis is the resorption of the fluid which ordinarily takes but a few days and indicates a subsidence of the inflammatory process. During this time, rest and firm bandaging of the joint are advisable. As soon as the pain subsides, voluntary motion is started, but weight-bearing is best postponed for at least a week or two. Cold, in general, limits edema due to trauma when applied early (in the first hour or two) though heat, by promoting the circulation, aids in its resorption once swelling develops. Cold or heat may be used for the relief of pain depending to some extent on the preference of the patient.

2. *Laceration of Joint Capsule.* The treatment of lacerations involving the joint capsule is, in reality, the same as that of any deep wound as already discussed in Chapter 14. If the injury is recent, and exploration and débridement are indicated, the wound is treated thoroughly, the joint cavity carefully inspected and irrigated, then the joint capsule *closed without drainage.* If 24 hours or more have elapsed since injury, and infection is already present, conservative measures, such as immobilization, cleanliness, and perhaps traction, are indicated; insertion of drains into cavities is as a rule to be condemned. Chemotherapy is most useful in preventing as well as in combating infection.

3. *Rupture of Ligaments* (*Sprain*). Sprains are to be suspected in every severe injury about the joint, especially if there is excruciating tenderness over the ligaments and not over the bone. Severe pain which develops on specific motions only also suggests a sprain if a fracture is not present. Detailed consideration of sprains will be found in Chapters 22 and 23.

4. *Injury to Articular Cartilage.* At the time of injury it is sometimes impossible to detect evidence of trauma to cartilage which may only become apparent later because chronic joint disability develops. When a fracture extends into a joint, as shown by x-ray, the joint cartilage is obviously injured and aspiration of the fluid in the joint will be bloody. Severe injuries of this type may be treated by suspension and traction or immobilization in a plaster cast, even if there is no displacement of fragments. Early motion

is also advisable. Treatment of any associated fracture is obviously important.

Injury to the semilunar cartilage of the knee is of a special type and may consist of rupture or tearing with or without dislocation. Injury to the semilunar cartilage frequently follows a severe sprain because of the intimate attachments of this cartilage to the joint capsule and ligaments. The internal semilunar cartilage is most commonly involved, especially following any severe twisting and abduction of the knee, such as catching the foot in a hole while running. The injury may consist of a detachment, tear, or crush. Sometimes the medial portion of the medial meniscus is displaced into the intercondylar notch, the so-called "bucket handle" type of lesion. If the cartilage is displaced, complete extension may be impossible and the usual local signs of acute injury will develop with severe pain and local tenderness. "Locking" of the knee with inability to extend the joint is a frequent manifestation. Occasionally, considerable clear, straw-colored fluid accumulates in the joint. Replacement often occurs spontaneously or may sometimes be achieved by careful flexion and rotation of the tibia, with or without anesthesia. Success is shown by the ability to completely extend the leg. The knee is then treated like acute synovitis except that in severe cases immobilization in plaster may be necessary. If, after six weeks of nonoperative therapy, symptoms persist, especially pain and instability, the damaged cartilage should be removed although operation should not be postponed over a year after the injury. Rupture of the *cruciate ligaments* of the knee sometimes occurs and is to be suspected when abnormal mobility in the anteroposterior direction is elicited. This is generally associated with tears of the medial collateral ligament. If such an injury is seen early and recognized, then surgical repair of the torn medial ligament should be carried out. Repair of the cruciate ligament is a complicated procedure and is not advised in the acute phase of the injury. Following surgical repair, immobilization in plaster is indicated for a period of three to four weeks, following which intensive exercises are necessary to strengthen the quadriceps muscle. When the indications are not sufficient to justify operation, then immobilization should be employed.
